With regard to the veins, Professor Owen points out that they are remarkable not only for their great capacity, which Hunter noticed, but also for their number and the immense plexuses which they form in different parts of the body, and above all for the almost total absence of valves. Tyson, he observes, has given a figure of the extensive venous plexus situated on the membrane investing the psoas muscles, and these have recently occupied the attention of Breschet and Von Baer. The inferior and superior venæ cavæ are not brought into communication by the vena azygos, as in other *Mammalia;* such veins in the usual situation in the chest would have been subject to compression between the arterial plexuses and the lungs. The venæ azygos are therefore represented by two venous trunks situated in the interior of the vertebral canal, where they receive the intercostal and lumbar veins, and finally communicate with the superior cava by means of a short single large trunk, which penetrates the parietes of the posterior and right side of the chest. Professor Owen concludes this interesting note to Hunter's 'Animal Economy' by clearing up the difficulty, which must have occurred to most, of accounting for the fact of so enormous an animal as the great whale being killed by such puny instruments as the harpoon and lance. "The non-valvular structure of the veins in the *Cetacea,*" says the Professor, "and the pressure of the sea-water at the depths to which they retreat when harpooned, explain the profuse and deadly hæmorrhage which follows a wound that in other *Mammalia* would be by no means fatal."

Respiratory System.—Phytophagous Cetaceans.—Professor Owen states that the peculiar form, structure, and position of the lungs have been so accurately described and figured by Raffles, Home, and Rüppell, that he has only to observe the close agreement with those accounts which the structure of the parts presented in the three Dugongs dissected by him. Daubenton and Humboldt, he remarks, describe and figure a precisely similar condition of the respiratory apparatus in the Manatee. Steller, he adds, describes the same extension of the lungs in the *Rytina,* and compares it with the lungs in the Bird, but without their fixation in the parietes of the chest, so characteristic of that class. Professor Owen is of opinion that the Chelonian reptiles perhaps offer a closer resemblance to the Herbivorous *Cetacea* in this respect; and he notices it as worthy of remark, that the air-cells of the lungs are larger in the Dugong than in any other mammals. In the Carnivorous *Cetacea,* the air-cells, he observes, are remarkably minute, and the lungs more compactly shaped and lodged in a shorter thorax.

"Existing," continues Professor Owen, "as both the Herbivorous and Carnivorous *Cetacea* do, under such peculiar circumstances—as air-breathing animals constantly dwelling in an element the access of which to the lungs would be immediately fatal—it might be supposed that the mechanism of the larynx, or entry to the air-passage, would be similarly modified in all the species, in order to meet the contingencies of their aquatic existence. But we can as little predicate a community of organisation in the structure of this part, as of the circulating or digestive system in the *Cetacea* of Cuvier. The Dugong and the Dolphin present, in fact, the two extremes in the Mammiferous class, in the development of the epiglottis, which is one of the chief internal characteristics of that class. In the true *Cetacea* and the *Delphinidæ* in particular, it is remarkable for its great length, and in the Dugong it can hardly be said to exist at all."

Professor Owen, after giving a minute and accurate account of the larynx, thus proceeds:—

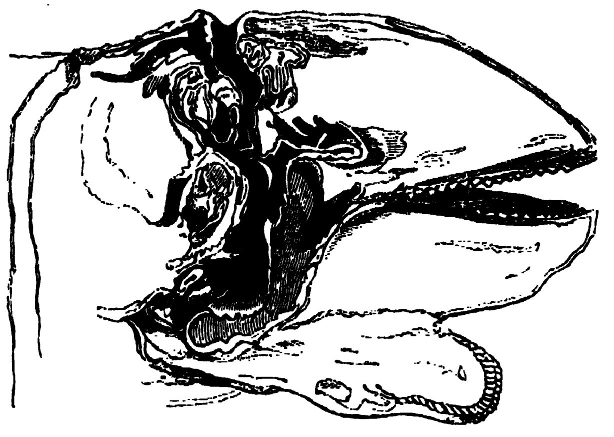
"Amongst the true *Cetacea,* we have observed that it is those which subsist on the lowest organised animal substance, as the *Balænidæ,* which approach the nearest to the herbivorous species, in having the additional complexity of the cæcum; and it is interesting to find that the same affinity is manifested in the structure of the larynx. The epiglottis and arytenoid cartilages, for example, are relatively shorter in the *Balænoptera* than in *Delphinus;* and as Mr. Hunter has observed, they are connected together by the membranes of the larynx only at their base; and not wrapped together or surrounded by that membrane as far as the apices, as in the Dolphins. In the *Balænoptera* also, the apices of these cartilages are not expanded, as in the Dolphins, but diminished to an obtuse extremity. These points of resemblance to the condition of the larynx in the Dugong and Manatee are carried still further in the Mysticete Whale, at least in the fœtus dissected by me, and in which both the epiglottis and arytenoid cartilages were relatively much shorter, and the thyroid cartilage larger and more convex than in the Piked Whale (*Balænoptera*). The thyroid cartilage is however a single piece in both genera of *Balænidæ,* though deeply notched above and below; and the larynx presents several interesting individual peculiarities, which however the minute and accurate descriptions and illustrations of this organ, in both the *Balænoptera* and *Balænæ,* published by Professor G. Sandifort, preclude the necessity of further dwelling upon."

The diaphragm, lungs, bronchi, and trachea present in the Zoophagous Cetaceans secondary modifications only, but important differences are exhibited in the nostrils, which serve to conduct the air from the atmosphere to the lungs. The necessity for the act of spouting seems to have led to the obliteration of the organ of smelling, and to the formation of a new organ especially destined to fulfil that act. Although this organ has only been studied thoroughly in the Dolphins, the probability is, that the apparatus in all the Zoophagous Cetaceans is the same.

If, says Baron Cuvier, we trace the œsophagus upwards, we find that when it arrives opposite the pharynx it appears to divide into two passages, one of which is continued onwards to the mouth, while the other ascends to the nose. Mucous glands and fleshy fibres, which constitute several muscles, surround the last-mentioned passage. Some of these are longitudinal, and arise from the circumference of the posterior orifice of the bony nostrils, and descend along that canal to the pharynx and its sides; the others, which are annular, appear to be a continuation of the proper muscles of the pharynx. The larynx rises into this passage in a pyramidal form, and the annular fibres have the power of constricting it. Mucous follicles, which pour out their secretion by conspicuous excretory orifices, prevail in this part. When the lining of the nasal passage has reached the vomer, it becomes of a peculiar texture, thin, smooth, and black, is apparently destitute of vessels and nerves, and very dry. A fleshy valve closes the two bony nasal canals at the upper or external orifice. It is formed of two semicircles attached to the anterior edge of that orifice, which it shuts by the agency of a very strong muscle lodged above the intermaxillary bones. To open it, there is a necessity for some foreign body to press against it from below; and when it is closed, it debars all communication between the nasal passages and the cavities above them, which cavities are two large membranous pouches formed by dark mucous skin, and very much wrinkled when empty; but when distended, they become of an oval shape, which in the Porpesse is about as large as a common wine-glass. These two pouches lie beneath the integument in front of the nostrils, and communicate with an intermediate space immediately above those nasal organs, whose external orifice is a transverse semilunar slit. Strong fleshy fibres expand and cover the whole upper surface of this apparatus, radiating from the entire circumference of the cranium, uniting above the two pouches, and adapted for compressing them forcibly. Now we will suppose that the Cetacean has taken into its mouth water which it wishes to eject: it first sets the tongue and jaws in motion as if it were about to swallow the water; but, shutting its pharynx, it forces the water to ascend into the nasal passages, where the annular fibres above mentioned accelerate its progress till it raises the valves and distends the membranous pouches above. The water, when once in the pouches, can be there retained till the animal wishes to spout. When that wish is present, the Cetacean closes the valve, and so prevents the descent of the water into the nasal passages, and forcibly compresses the pouches by means of the muscular expansion which overspreads them. The water, compelled then to escape by the narrow semilunar aperture, is projected to a height which corresponds to the amount of the pressure applied.

In the case of the Spermaceti Whale, it appears that the animal occupies about a seventh of its time in breathing; and when it rises after long intervals, an enormous column of air must rush into the lungs and aërate a vast quantity of blood for the reservoir described by Hunter. In ordinary mammals, man and the quadrupeds for instance, respiration is momentarily going on, and enough air only is inhaled to oxygenate the blood requisite for a few pulsations.

The spout-hole is simple in the Dolphins, and situated, as seen in the cut, towards the top of the head: the same simplicity exists in that of the Cachalots, but it is situated at the upper extremity of the snout. In the Whalebone Whales it is double, opening towards the summit of the head, as in the Dolphins, in a crescentic form whose convexity is sometimes anterior and sometimes posterior.



Vertical section, exhibiting the tongue, larynx, and nostrils of the Porpesse. ('Catalogue of the Physiological Series' (Mus. Coll. Chir.), vol. ii. pl. 29, p. 163.)

Uropoietic System.—Professor Owen observes, that if we were acquainted with the structure of the urinary organs of the Herbivorous *Cetacea*, as it is exemplified in the Dugong alone, we should have to establish as marked a distinction in this respect between them and the true *Cetacea* as in the preceding organic systems. Instead of the numerous and minute lobuli or renules into which the kidney is subdivided in the Dolphins and Whales, it presents in the Dugong a simple compact form with an unbroken external surface; the tubuli uriniferi terminate upon two lateral series of eleven mammillæ, which project into a single elongated cavity or pelvis, from which the ureter is continued. In the Northern Manatee however, Steller, whose accuracy Professor Owen justly notices, describes the kidney as being subdivided like that of the Seal and Sea-Otter. A similar lobulated structure is also ascribed by John Hunter, in his paper on Whales, in 'Phil. Trans.' (1787), to the Manatee, including it, with the Seal and White Bear, among the animals occasionally inhabiting the water. Daubenton, in his anatomical description of the *Manatus Americanus*, merely notices the kidneys as oblong, and placed opposite to each other; nor does his figure give any indication of lobulated structure; neither does Sir Everard Home mention such structure in his Anatomy of the Manatee in 'Phil. Trans.' (1821). This want of uniformity in the structure of the kidney in the Herbivorous *Cetacea* is however, Professor Owen adds, of less moment with reference to their natural affinities; since in the Pachyderms we find some species, as the Rhinoceros, and though in a less degree, the Elephant, presenting a subdivided kidney; while others, as the Tapir and Hog, have it entire.

In the fœtus of the Dolphin, according to Müller, the lobules of the kidney consist principally of convoluted uriniferous ducts, extending from the apex to the circumference of the lobule; the intertwinings of the tubuli are greatest in the intercortical portion. It is a curious fact, Professor Owen remarks, that the supra-renal gland in the Porpesse presents a certain resemblance to the kidney in its lobulated exterior; but, he adds, the analogy extends no farther, for on making a section of this part it was found to consist of the usual continuous compact substance.

Generative System.—John Hunter remarks that the organs of generation of this order of animals come in both sexes nearer in form to those of the Ruminants than of any others; and this similarity is particularly remarkable in the female; in the male their situation varies on account of the modification of the external form of the body.

The female organs in the *Rytina* have been described by Steller; and Sir Everard Home has given an account of those of the Dugong. ('Phil. Trans.,' 1820.)

Hunter, in his paper on Whales has entered particularly into the structure of those of the Zoophagous Cetaceans. The period of uterine gestation does not appear to be certainly known; the number of young is generally considered not to exceed one, there being but two nipples; the glands for the secretion of milk are two, one on each side of the mesial line of the belly at its lower part. The milk is very rich, like that of a cow to which cream has been added.

Professor Owen remarks, that much stress has been recently laid on the supposed existence which the muscles surrounding the mammary gland afford in the act of suckling, by compressing the gland and ejaculating the milk accumulated in the dilated receptacle or reservoir; but he observes that, considering how great the pressure of the surrounding water must be upon the extended surface of the mammary gland, it may readily be conceived, that when the nipple is grasped by the mouth of the young, and the pressure removed from it by the retraction of the tongue, the milk will be expelled in a copious stream by means of the surrounding pressure alone, independently of muscular aid. The Professor adds, that the intimate structure of the mammary gland in the Zoophagous *Cetacea* is essentially the same as in the *Ornithorhynchus*, being composed of an innumerable quantity of cæcal tubes; these are however shorter than in the *Ornithorhynchus*, and their glandular parietes are firmer; they are well shown in the figure of the mammary gland in a young Piked Whale (*Balænoptera rostrata*) given by Müller in his seventeenth plate, fig. 2., and according to that author present, after the *Ornithorhynchus*, the simplest structure of the mammary gland in the entire mammiferous series of animals.

Brain, Nervous System, and Senses.—The brain is well formed. In the Porpesse and the common Dolphin it has been stated to be as highly developed as in any mammiferous quadruped. In the greater whales there is reason for supposing that the ratio of the weight of the brain to that of the body is $\frac{1}{3000}$. In the smaller Cetaceans it is not diminished to a proportionate size, as its extraordinary development in the Dolphin testifies.

Smell.—Hunter observes that in many of the Whale Tribe there is no organ of smell at all, and in those which have such an organ, it is not that of a fish, therefore probably not calculated to smell water. It becomes difficult therefore, he remarks, to account for the manner in which such animals smell the water; and why the others should not have had such an organ, which seems to be peculiar to the large and small Whalebone Whales (*Balæna mysticetus* and *Balænoptera rostrata*); the organ, in those which have it, he adds, is extremely small, when compared with that of other animals, as well as the nerve which is to receive the impression.

Taste.—The complicated and indeed delicate structure of the tongue in the Phytophagous Cetaceans indicates that they must enjoy the sense of taste, although the tongue is capable of but slight motion.

But it has been doubted whether the Zoophagous Cetaceans are endowed with a special organ for the enjoyment of this sense. No fossulate nor conical papillæ are present in the tongue of the Dolphin or of the Porpesse; slight elevations, the middle of which appears to be perforated, are only perceptible, and the fringed edges would seem to lead to the notion that their object is more intended for furthering the sensations of touch.

John Hunter states that the tongue, which is the organ of taste, is also endowed with the sense of touch. He found the tongue in the Porpesse and Grampus firm in texture, composed of muscle and fat, pointed and serrated on its edges like that of a hog. In the Spermaceti Whale, he says, it was almost like a feather-bed. In the Piked Whale it was but gently raised, hardly having any lateral edges, and its tip projecting but little, yet like every other tongue, composed of muscle and fat. He supposes that the tongue of the large Whalebone Whale rises in the mouth considerably; the two jaws in the middle being kept at such a distance on account of the whalebone, so that the space between, when the mouth is shut, must be filled with the tongue.

Sight.—The eye in the Herbivorous Cetaceans only is provided with a nictitating membrane, or lateral lid; that of the Zoophagous or Spouting Cetaceans has no lachrymal glands, but the lids are furnished with glands for a mucous secretion adapted for lubricating the sclerotic coat.

John Hunter states that the eye in this tribe is constructed upon nearly the same principle as that of the quadrupeds, differing however in some circumstances, by which it is probably better adapted to see in the medium through which the light is to pass. It is upon the whole small for the size of the animal. The lids have but little motion, and consist not of loose cellular membrane, as in common quadrupeds, but rather of the common adipose membrane of the body; the connection however of their circumference with the common integuments is loose, the cellular membrane being less loaded with oil, which allows of a slight fold being made upon the surrounding parts in opening the eyelids. This is not to an equal degree, he adds, in them all, being less so in the Porpesse than in the Piked Whale. A detailed account of the anatomy of the eye in whales will be found in Hunter's paper.

Hearing.—There is no external concha, but the ear is constructed much upon the same principle as in the quadruped; there are however certain differences which the reader will find set forth in Hunter's paper. The sense seems to be fairly developed, and whale-fishers experience no small difficulty from the warning given by both eye and ear. It has however been stated that the Greenland Whale, though not without a nice sense of hearing, remains insensible to the report of a cannon.

Touch.—The sensation of touch must be lively, though it is a commonly received opinion that the common Dolphin, notwithstanding its delicate epidermis, is not very sensible to tactile impressions. Messrs. Breschet and Roussel de Vauzème distinguish the following constituents in the skin of the Cetaceans:—1. Derm, or corium, a dense fibrous cellular texture, which contains and protects all the other parts of the skin. 2. The papillary bodies, consisting of papillæ covered by the derm. 3. The sudorific apparatus, consisting of soft, elastic, spiral canals, which extend through the entire thickness of the derm, and open in the intervals of the papillæ by an orifice, closed generally by a small epidermic valve. 4. The inhalent apparatus, 5. The mucous apparatus. 6. The colorific apparatus.

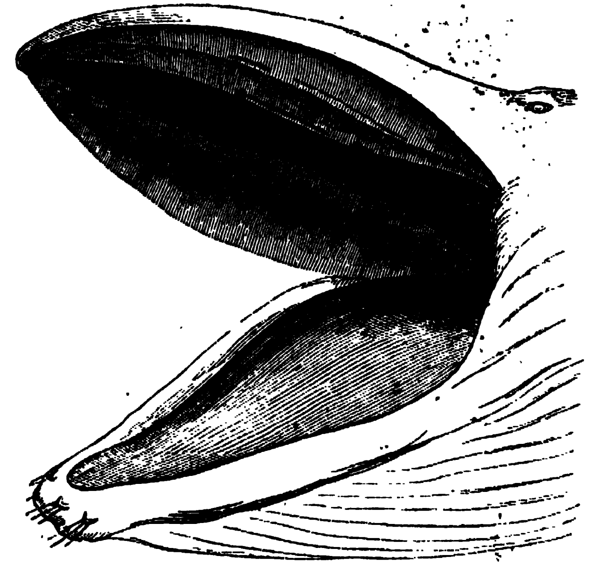
According to Hunter, the reticular network containing the blubber, which is described by him as fine in the Porpesse, Spermaceti, and large Whalebone Whale (*Balæna*), and coarse in the Grampus and small Whalebone Whale (*Balænoptera*), forms part of the skin.

In giving some illustrations of this large family we shall follow the arrangement of Dr. J. E. Gray as indicated above.

The following is a synopsis of the character of the genera of the first family *Balænidæ* :—

a. Dorsal fin none. Belly smooth. Baleen elongate, slender.
  1. *Balæna.*
b. Dorsal fin distinct. Belly plaited. Baleen broad, short.
  2. *Megaptera.* Pectoral fins elongate. Dorsal fin low.
  3. *Balænoptera.* Pectoral fins moderate. Dorsal fin falcate, ¾ length from nose. Vertebræ 54 or 64.

It is in the genus *Balæna* that the baleen, or whalebone, is most highly developed. John Hunter describes this extremely elastic animal substance as being of the same nature as horn, a term which he uses to express what constitutes hair, nails, claws, feathers, &c. It consists, he remarks, of thin plates of some breadth and in some of very considerable length, their breadth and length in some degree corresponding to one another; when longest they are commonly the broadest, but not always so. The plates differ in size in different parts of the same mouth, more especially in the large Whalebone Whale. "They are placed," continues Hunter, "in several rows, encompassing the outer skirts of the upper jaw, similar to teeth in other animals. They stand parallel to each other, having one edge towards the circumference of the mouth, the other towards the centre or cavity. They are placed near together in the Piked Whale, not being a quarter of an inch asunder, where at the greatest distance, yet differing in this respect in different parts of the same mouth; but in the Great Whale the distances are more considerable. The outer row is composed of the longest plates; and these are in proportion to the different distances between the two jaws, some being 14 or 15 feet long and 12 or 15 inches broad; but towards the anterior and posterior parts of the mouth they are very short, they rise for half a foot or more, nearly of equal breadths, and afterwards shelve off from their inner side until they come near to a point at the outer: the exterior of the inner rows are the longest, corresponding to the termination of the declivity of the outer, and become shorter and shorter till they hardly rise above the gum. The inner rows are closer than the outer, and rise almost perpendicularly from the gum, being longitudinally straight, and have less of the declivity than the outer. The plates of the outer row laterally are not quite flat, but make a serpentine line; more especially in the Piked Whale the outer edge is thicker than the inner. All round the line made by their outer edges runs a small white bead, which is formed along with the whalebone, and wears down with it. The smaller plates are nearly of an equal thickness upon both edges. In all of them the termination is in a kind of hair, as if the plate was split into innumerable small parts, the exterior being the longest and strongest. The two sides of the mouth composed of these rows meet nearly in a point at the tip of the jaw, and spread or recede laterally from each other as they pass back; and at their posterior ends in the Piked Whale they make a sweep inwards, and come very near each other, just before the opening of the œsophagus. In the Piked Whale there were above 300 in the outer rows on each side of the mouth. Each layer terminates in an oblique surface, which obliquity inclines to the roof of the mouth, answering to the gradual diminution of their length; so that the whole surface, composed of these terminations, forms one plane, rising gradually from the roof of the mouth: from this obliquity of the edge of the outer row we may in some measure judge of the extent of the whole base, but not exactly, as it makes a hollow curve, which increases the base. The whole surface resembles the skin of an animal covered with strong hair, under which surface the tongue must immediately lie when the mouth is shut; it is of a light-brown colour in the Piked Whale, and is darker in the Large Whale. In the Piked Whale, when the mouth is shut, the projecting whalebone remains entirely on the inside of the lower jaw, the two jaws meeting everywhere along their surface; but how this is effected in the Large Whale I do not certainly know, the horizontal plane made by the lower jaw being straight, as in the Piked Whale; but the upper jaw being an arch cannot be hid by the lower. I suppose therefore that a broad upper lip, meeting as low as the lower jaw, covers the whole of the outer edges of the exterior rows. The whalebone is continually wearing down, and renewing in the same proportion, except that when the animal is growing it is renewed faster and in proportion to the growth. The formation of the whalebone is extremely curious, being in one respect similar to that of hair, horns, spurs, &c.; but it has besides another mode of growth and decay equally singular. These plates form upon a vascular substance, not immediately adhering to the lower jaw-bone, but having a more dense substance between, which is also vascular. This substance, which may be called the nidus of the whalebone, sends out (the above) thin broad processes, answering to each plate, on which the plate is formed, as the cock's spur or the bull's horn, on the bony core, or a tooth on its pulp; so that each plate is necessarily hollow at its growing end, the first part of the growth taking place on the inside of this hollow. Besides this mode of growth, which is common to all such substances, it receives additional layers on the outside, which are formed from the above-mentioned vascular substance extended along the surface of the jaw. This part also forms upon it a semi-horny substance between each plate, which is very white, rises with the whalebone, and becomes even with the outer edge of the jaw, and the termination of its outer part forms the bead above mentioned. This intermediate substance fills up the spaces between the plates as high as the jaws, acts as abutments to the whalebone, or is similar to the alveolar processes of the teeth, keeping them firm in their places. As both the whalebone and the intermediate substance are constantly growing, and as we must suppose a determined length necessary, a regular mode of decay must be established, not depending entirely on chance, or the use it is put to. In its growth three parts appear to be formed: one from the rising core, which is the centre; a second on the outside; and a third being the intermediate substance. These appear to have three stages of duration; for that which forms on the core, I believe, makes the hair, and that on the outside makes principally the plate of whalebone. This, when got a certain length, breaks off, leaving the hair projecting, becoming at the termination very brittle; and the third or intermediate substance, by the time it rises as high as the edge of the skin of the jaw, decays and softens away like the old cuticle of the sole of the foot when steeped in water. The use of whalebone, I should believe, is principally for the retention of the food till swallowed; and I suppose the fish they catch are small when compared with the size of the mouth." (Hunter 'On Whales.')



View of the inside of the jaws of a fœtal *Balænoptera*, showing the arrangement of the Whalebone. (Owen, 'Odontography,')

The following notes by Dr. J. E. Gray contain the result of the most recent observations on this curious production in the *Cetacea* :—

"The baleen, or whalebone, has generally been considered as the teeth of the whale; but this must be a mistake, for Mr. Knox observes: 'In the fœtal *B. mysticetus* 60 to 70 dental pulps were found on each side of each jaw, making the whole number amount to from 260 to 300. The preparation (No. 56) exhibits a portion of this gum with 12 pulps. Had these pulps been confined to the upper jaw, and corresponded to the number of baleen plates, it would have formed a strong analogy between the baleen and teeth; but the number of baleen plates in the whale greatly exceeds the number of dental pulps; and the lower jaw, which contained an equal number of pulps with the upper, has neither teeth nor baleen in the adult whale. Their presence therefore in the fœtal *Mysticetus* forms one of the most beautiful illustrations of the unity of organisation in the animal economy. The teeth in the *Balæna* never cut the gum, but become gradually re-absorbed into the system; the very cavity in which the gums were lodged disappears; whilst, to suit the purposes of nature, the integumentary system furnishes the baleen, which is evidently a modified form of hair and cuticle.' (Knox, 'Cat. Whales,' 22.) Professor Eschricht has shown also that the fœtus of *Megaptera Boops* ('Danish Trans.,' xi. t. 4, 1845) has numerous teeth on the edge of the jaw, though they are never developed. I am inclined to regard the baleen as a peculiar development of hair in the palates of these animals, and somewhat analogous to the hair found in the palates of the genus *Lepus*.

"From the examination I have been able to make of the baleen of *Balænoptera rostrata*, and of different masses of small blades of *Balæna australis*, it would appear as if there was, at least in these two species, two series of baleen on each side of the palate; the external series being formed of large triangular blades placed at a certain distance apart; and the internal, in *Balænoptera rostrata*, formed of smaller, much thinner, triangular pieces, placed much closer together, and forming a very dense screening apparatus; and in *Balæna australis* the inner series is formed of numerous separate narrow strips of whalebone, each ending in a pencil of hairs, which vary in size from that of small twine to that of tape, half an inch wide: these are placed behind the others, and gradually increase in size from the innermost to the broad external series.

"The baleen, or whalebone, affords good characters for the separation of this family into sections. Mr. Knox ('Cat. Prep. Whale,') gives the best account of the development, position, and distinction between the baleen of the whales of the North Sea which has come under my observation; and it agrees with the observations I had made on the subject before I could procure his pamphlet.

"In *Balæna maximus*, Knox (*Physalus Antiquorum*), 314 external or labial plates (baleen) were counted on each side. Towards each extremity these plates degenerate into bristles, and admit of being counted with difficulty. Towards the mesial line the baleen as a mass diminishes gradually in depth, giving the whole palatine surface an elegant arched form. The 314 external or labial plates do not extend to the whole extent in a transverse direction, but a system of numerous small and narrow plates succeeds the external ones. For each external plate twelve (internal) smaller ones could be easily counted; so that the number of plates which could be counted, and not including the bristly terminations towards the snout, pharynx, and mesial line, stands thus: external or labial plates 314; internal small plates, corresponding to each external one, 12; total number of baleen plates 3768. The longest plate of baleen is placed about the centre of each of the sides, and measured 26 inches in length, and 15 inches in breadth. The substance when recent is highly elastic and very heavy: the whole weighed nearly two tons.

"It is short or long according to the species of whale, being modified entirely by the more or less arched form of the upper jaw. Mr. F. Knox first pointed out this curious and important fact. The usual conclusion come to by all persons was, that the size of the whale corresponded to the length of the bone or baleen. Now, this is only good with regard to one species of whale, and not at all to the whole group of Whalebone Whales. (Knox, 'Cat. Prep. Whale,' 8.)

"In *Balæna minimus*, Knox (*Balænoptera rostrata*), 307 external or labial (baleen) plates can be counted on each side. Towards each extremity these plates degenerate into fine bristles, which were not counted. The plates hang perfectly parallel with each other, and from their closeness and fringed lingual aspect must act as a very perfect filter in collecting the minute molluscous animals, and at the same time enable the whale to eject the water. The food of the whale is still a much disputed point. It is now generally admitted that the *Mysticetus* lives only on small *Medusæ*, shrimps, &c., but that the other species of Whalebone Whale devour inconceivable quantities of fish; for instance, M. Desmoulins states that '600 great cod and an immensity (probably as many thousands) of pilchards have been found in the stomach of a single Rorqual.'

"Mr. F. Knox, in dissecting the *Balæna maximus*, saw no cavity in the course of the viscera which could have contained six cod of ordinary size; that of *B. minimus* was empty, although the Frith of Forth, particularly at and above Queensferry, abounds at all seasons with herrings and other fishes and their fry. The want of teeth by no means renders it impossible that the *Balæna* with baleen can live on large fishes; but the extreme narrowness of the gullet (that of *B. maximus* barely allowed the passage of the closed human hand, and that of *B. minimus* was certainly narrower than that of an ordinary sized cow), added to the want of teeth and the want of proper authenticated information on the subject, are strong arguments in favour of the hypothesis that they do not. (Knox, 'Cat. Prep. Whale,' 16.)

"The thickness of the plate of baleen depends on the number of bristles. In the baleen of *B. maximus* there are 506 bristles in the thickness of the plate, and by a rude enumeration there appeared to be at least 130 bristles in each inch. The whole breadth of the plate being 5½ inches gives us 747 bristles entering into its composition. These bristles are matted together to the extent of 11 inches on the external and 5 inches on the internal margins by a substance like minute laminæ or scales, and which may be seen by the aid of a microscope to invest the free bristles at the fringed extremity of the plate. We have often observed the facility with which some baleen can be split up, and were struck with the fact that the baleen of *B. maximus* would not split. The removal of the external lamina in the plate under description shows the cause of this: about 6½ inches from the root of the plate, many of the bristles have deviated from their direct parallel inclination, and become intimately twisted and interwoven with each other. It has been attempted to prove the age of the whale from an examination of the baleen, in the same manner as we judge of the age of cattle by certain annulated markings on the horns. On the plate before us we can distinctly perceive numerous transverse lines crossing the course of the bristles at right angles. If these transverse lines indicate a periodical check to the growth of the baleen, then the age of the *B. maximus* would be 800 to 900 years old, that being the number of transverse lines on the longest plate of baleen. (Knox, 'Cat. Prep. Whale,' 9.)

"The whalebone of the smooth-bodied whales without any back fins (*Balæna*) is elongate, much longer than broad at the base, and gradually attenuated, and edged with a fringe of equal lengthened fine soft bristles. The baleen is internally formed of a thin layer of fibres, covered on each side with a thick coat of 'enamel;' when dry and out of the mouth the blades are flat.

"The whalebone of the plaited-bellied whale with a bunch (*Megaptera*) or a dorsal fin (*Balænoptera*) is short, broad, triangular, not much longer than broad at the base, and rapidly attenuated; and is edged with a series (sometimes rather crowded) of elongate rigid unequal bristle-like fibres, which become much thicker and more rigid near and at the tip. The baleen is internally formed of a more or less thick layer of thick fibres, covered on each side with a thin layer of enamel, and when dry and out of the palate they are curled up and somewhat spirally twisted.

"The baleen of the *Balæna* is alone designated Whalebone (or rather Whale-Fin, as it is usually called) in commerce. The baleen of the other genera of this family is called Finner-Fin or Humpback-Fin. The wholesale dealers in baleen, in the 'London Directory,' are called Whale-Fin Merchants, and whalebone occurs under the name of Whale-Fin in the 'Price-Current.' In the 'London New Price-Current,' for 1843, the South Sea Whale-Fin varied during that year from 200*l.* to 305*l.* per ton, and there is no price named for Greenland Whale-Fin. (McCulloch, 'Com. Dict.' i. 1344.)

"The baleen was formerly thought to be the tail of the animal. (Blackstone, 'Commen.' i. 233, quoted by McCulloch, 'Com. Dict.' 1344."

Balæna mysticetus (the Right Whale). It is the *B. Grœnlandica* of Linnæus; *B. vulgaris* of Brisson; *B. Rondeletii* of Willughby; the Right, Whalebone, Common, or Greenland Whale of English writers. One variety is called the Nord Kapper or Nord Caper, another the Rock-Nosed Whale.

Description.—Colour velvet-black, gray, and white, with a yellow tinge. Back, greater portion of the upper jaw, part of the lower, fins, and tail, black; lips, fore part of lower jaw, sometimes a little of the upper, and a portion of the abdomen, white; eyelids, junction of the tail with the body, part of the axilla of the flippers, &c., gray. The older the whale, the more white and gray is there upon it; some are piebald all over. The surface of the body is rather furrowed. The head is very large, forming nearly a third of the whole bulk, the under part, the outline of which is given by the jaw-bone, flat. The lips inclose the cavity of the mouth; the upper jaw is bent down at its edges like a boat upside down, so as to shut in the front and upper parts of the cavity. On the most elevated part of the head are situated the blow-holes, two longitudinal apertures like the holes in the belly of a violin, and from 8 to 12 inches long. The baleen is very long, ranging from 9 to 12 feet. There are upwards of three hundred of these plates of whalebone on each side of the jaw, enclosing the tongue between their lower extremities, and themselves covered by the lower lip. The body is thickest a little behind the flippers, near the middle of its whole length, whence it gradually tapers conically towards the tail, and slightly towards the head. There is no dorsal fin. The flippers, about 9 feet long and 5 feet broad, are placed about two feet behind the angle of the mouth, and cannot be raised above a horizontal position. The horizontal tail is flat and semilunar, indented in the middle; the two lobes somewhat pointed and turned a little backwards. The eyes, not much larger than those of an ox, have a white iris, and are situated on the sides of the head about a foot obliquely above and behind the angle of the mouth. The sense of sight appears to be acute in the water, but not above it. The size of this whale has been supposed to have been greatly exaggerated by old statements. Eighty and 100 feet were mentioned as a frequent length, and many accounts more than doubled that measurement. At present 65 or 70 feet appear to be the extreme length of a full grown Mysticete. The Rev. Dr. Scoresby, who has elucidated the history of this whale as satisfactorily as Mr. Beale has that of the Sperm-Whale, and who was personally concerned in the capture of 322, found not one that exceeded 60 feet. It should be remembered however, in criticising old accounts, that the great persecution which these animals have long undergone and still undergo, while it reduces their numbers, is very unfavourable to longevity.

The habitat usually assigned to this whale is most extensive: thus, M. Lesson states that it inhabits all the seas of the globe, especially the two poles; but it is not improbable that the Whalebone Whale or Black Whale of the South Seas (*Balæna australis*, Desmoulins, *B. antarctica*, Less.), which has every appearance of being distinct, and moreover of being infested with parasitical cirrhipedes (*Tubicinella*, *Coronula*, &c.) of different species from those which infest the Greenland Whale, has been mistaken for the last named cetacean. Multitudes of the Southern *Balæna* were seen by Captain James Ross, R.N., in very high southern latitudes during his last expedition.

This species seems to hear acutely any noise made in the water, such as splashing, &c. in calm weather; but a sound produced in the air, a loud shout for instance, when the whale is only at the distance of a ship's length, is disregarded. The usual rate of swimming seldom exceeds four miles an hour, but they will descend when harpooned at a velocity of seven or eight miles an hour, and one of these whales when alarmed can sink in five or six seconds far beyond the reach of a human enemy. The Mysticete seldom remains at the surface to breathe longer than two minutes, during which period it blows eight or nine times. It then descends for five or ten minutes; sometimes, when on its feed, for fifteen or twenty minutes. Though Dr. Scoresby states that it has no voice, it makes, he observes, a loud noise in blowing. The spout is ejected some yards high, and has the appearance of a puff of smoke at a distance. They blow strongest, densest, and loudest when alarmed, or after a long stay under water.

A very considerable portion of the feeding-grounds is occupied by what is termed 'green water,' which swarms with minute life, and has been carefully examined and described by Dr. Scoresby. The smallness of the gullet is only fitted for swallowing small animals, such as the *Clio borealis*, numerous specimens of which (the 'Whale's Food' of the Greenland Whalers) will be found in the preparation No. 323 A of the Physiological Series of the Museum of the Royal College of Surgeons in London. This small mollusk is said to constitute the chief support of the Mysticete, and the structure and disposition of the whalebone-plates explain how these or any other small species of animal are retained in the capacious mouth of their devourer, while the water taken in along with them drains through the interstices of the plates. When the Mysticete feeds, it swims rapidly below the surface with open jaws; a stream of water enters them, and with it myriads of small marine animals; the water finds an outlet at the sides, but the thick internal hairy apparatus of the whalebone does not permit one of these animals to escape.

Nine or ten months is supposed to be the period of utero-gestation, and the mother is so attached to her young one, or 'sucker,' as it is termed, that it is often struck as a snare to the affectionate parent, for she will not leave it, and falls a victim to her maternal love. Dr. Scoresby relates instances of this kind which cannot be perused, much less witnessed, without great pain by any person of ordinary humanity. Such a mode of capture seems hardly justifiable, whilst it must be ruinous to future prospects.

This species is generally found alone or in pairs, excepting when many individuals are attracted to some abundant feeding-ground or to a desired locality, such as the vicinity of icebergs.

To the Esquimaux and the Greenlander this species is all in all. They eat the flesh and fat with indescribable relish. The membranes of the abdomen serve them for clothing, and the thin transparent peritoneum admits light through the windows of their huts whilst it keeps out the weather. The bones are made into props for their tents, or aid in the formation of their boats, and supply them with harpoons and spears for the capture of the seal and greater sea-birds. The sinews, divided into filaments, are used as thread for sewing their dress, &c. Some have stated that pickled and boiled blubber is palatable, and that the tail, first parboiled and then fried, is agreeable eating. The flesh of the young whale is said to be by no means indifferent food. To civilised nations, the oil made from its fat or blubber, and the whalebone, have long made it a great commercial object. [FISHERIES, in ARTS AND SC. DIV.]

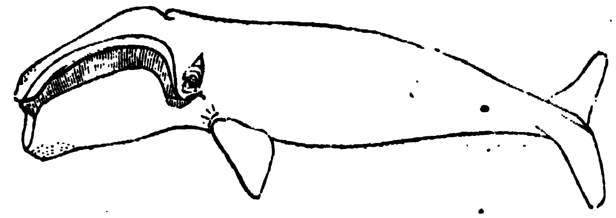
Greenland Whale (*Balæna mysticetus*).

B. marginata, the Western-Australian Whale, has very long and slender baleen, with a rather broad black edge on the outer or straight side. From the character of the baleen Dr. Gray considers this a distinct species.

B. australis, the Cape Whale. It is the Right Whale of South Sea Whalers, the Southern Whalebone Whale of Nunn, the Common Black Whale of Sir James Ross. It inhabits the South Seas, and is of a uniform black colour.

B. Japonica, the Japan Whale. It is an inhabitant of the coasts of Japan, which it visits periodically. Its head is covered with barnacles. Only the baleen has been seen in England. The species has been described from Chinese drawings.

B. antarctica, the New Zealand Whale. A species described by Dr. J. E. Gray as *B. Antipodarum*, from a very accurate drawing of a specimen taken in Jackson's Bay, New Zealand. It is the Tuku Peru of the natives. The specimen was 60 feet in length. The following cut is reduced from Dr. Gray's plate.



New Zealand Whale (*Balæna Antipodarum*). Gray.

B. gibbosa, the Scrag-Whale, is regarded as a species by Dr. J. E. Gray. It is an inhabitant of the Atlantic Ocean. "It is near akin to the Finback, but instead of a fin upon its back, the ridge of the after part of its back is scragged with half-a-dozen knobs or knuckles." (Dudley.)

The remaining genera of the *Balænidæ* have either fins or humps on their backs, and are called Finners and Hump-Backs.

The genus *Megaptera* includes the Hump-Backed Whales. They are easily known from the Finners in being shorter and more robust, the skull nearly one-fourth the entire length, the head wider between the eyes, the mouth larger, the lip warty, and the nose large and rounded; the plaits of the belly and throat are broad. The skull is intermediate between that of *Balæna* and *Balænoptera*.

M. longimana, Johnston's Hump-Backed Whale. It was described by Dr. Johnston from a specimen cast ashore at Newcastle. It is an inhabitant of the North Sea, and has been taken at the mouth of the Maas. It is the *Balæna longimana* of Rudolphi, and the *Balæna Boops*, or Keporkak, of Eschricht, who says it is the most common whale in the Greenland seas.

M. Americana, the Bermuda Hump-Back, is of a black colour, with a white belly, and has its head covered with tubercles. It is the *Balæna nodosa* of Bonnaterre. It is found at Bermuda from March to the end of May, when it departs. The baleen of this whale is extensively imported from Bermuda.

M. Poeskop, the Poeskop, or Cape Hump-Back. It is the Rorqual du Cap of Cuvier, the *B. Lalandii* of Fischer, and *B. Capensis* of Andrew Smith; the Hump-Backed Whale of Ross's 'Antarctic Voyage.' It is an inhabitant of the seas of the Cape of Good Hope.

M. Kuzira, the Kuzira. It inhabits the Japanese seas.

Balænoptera rostrata, the Pike-Whale. It is the *Balæna rostrata*, Müller; *Rorqualus rostratus*, Dekay; *Balænoptera microcephala*, Brandt; *Rorqualus Boops*, F. Cuvier. It is of a black colour, underneath of a reddish white. It inhabits the North Sea, and has been found in New York Bay, at Valognes in France, and a specimen was taken in the Thames at Deptford.

Physalus Antiquorum, the Razor-Back. It is the *Balæna Antiquorum* of Fischer, and probably the Great Northern Rorqual of Knox and Jardine; the Rorqual de la Mediterranée of Cuvier. It is of a slate-gray colour, whitish beneath. The baleen is slate-coloured, the under edge blackish, the inner edge pale-streaked. It is an inhabitant of the North Sea, and is sometimes found on the coasts of Great Britain. There is a skeleton at Black Gang Chine in the Isle of Wight 75 feet long. It was taken in 1842. A specimen was taken at Berwick in 1831. There is a skeleton of one also at Plymouth 74¼ feet long. This animal was found floating in Plymouth Sound on the 2nd of October 1831. It is stated to have been 102 feet long and 75 feet in circumference. This specimen was taken round the country in three caravans. Dr. J. E. Gray refers the skeleton of the whale now in the Edinburgh Botanic Gardens to this species. It was 80 feet long, and was taken off North Berwick in 1833.

P. (*Rorqualus*) *Boops* of Gray has been taken off the coast of Wales. The length of the specimen in the British Museum is 38 feet; the head is 9 feet long, the vertebræ are 60 in number, and there are 15 pairs of single ribs. It was taken in 1846, and was mentioned in the papers of the day as a Spermaceti Whale.

P. (*Rorqualus*) *Sibbaldii*. A specimen of this species exists in the museum at Hull. It is 50 feet long.

P. fasciatus, the Peruvian Finner, described by Tschudi, has been found on the coasts of Peru.

P. Iwasi, the Japan Finner. It is very rare; one was cast ashore at Kii in 1760. It was 25 feet long.

P. antarcticus, named from the baleen of a New Zealand species by Dr. J. E. Gray.

P. Brasiliensis, the Bahia Finner. Named from baleen; brought from Bahia.

P. australis, Southern Finner, inhabits the seas of the Falkland Islands.

The family of CATODONTIDÆ includes the Toothed Whales. The genera are as follows:—

Catodon. Dorsal hump rounded. Blowers on front of truncated head. Skull elongate.

Kogia. Dorsal hump. Blowers (?). Skull short, broad.

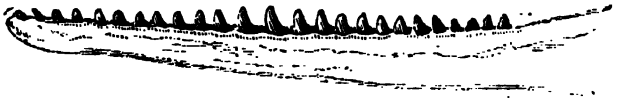
Physeter. Dorsal fin falcate. Blower on back of forehead. Skull elongate.

There has been much discussion about the genera and species of this family. We shall however follow the 'British Museum Catalogue,' adding the more common synonyms of the species.

Catodon macrocephalus, Northern Sperm-Whale. This is the *Physeter macrocephalus* of Linnæus; the Sperm-Whale, the Spermaceti Whale, the Blunt-Headed Cachalot of English writers. It is the *Physeter Trumpo* of Bonnaterre; the *Catodon Trumpo* of Gerard; the *Physeter gibbus* of Schreber; *Cetus macrocephalus* of Oken.

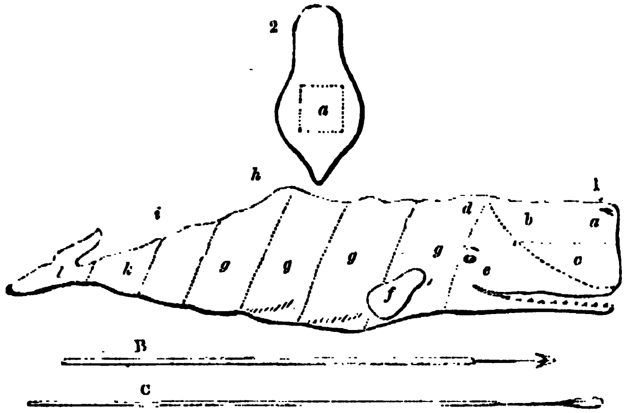
The colour of this animal is black, becoming whitish below.

The subjoined cut of the jaw is from F. Cuvier, who gives it from the skeleton in the Paris Museum, and is confined to the lower jaw only; from which it may be inferred, that in the French specimen there is no appearance of teeth in the upper jaw: in the lower there are 27 on each side=54.



Teeth of Cachalot.

To render the following description more intelligible we prefix a cut from Mr. Beale's work on the Sperm-Whale, which is by far the most accurate published figure extant of the Spermaceti Whale.



Spermaceti Whale (*Catodon macrocephalus*).

1, Outline of the entire form; 2, anterior aspect of the head; *a*, nostril, or spout-hole; *b*, situation of the case; *c*, the junk; *d*, bunch of the neck; *e*, eye; *f*, fin; *g*, spiral strips or blanket pieces; *h*, the hump; *i*, the ridge; *k*, the small; *l*, the tail or flukes.

B, a harpoon. C, a lance.

a, in fig. 2: the lines forming the square are intended to represent the flat anterior part of the head.

The head presents a very thick blunt extremity, constituting about a third of the whole length of the animal; at its junction with the body is a large protuberance on the back called 'the bunch of the neck.' Immediately behind this is the thickest part of the body, which from thence gradually tapers off to the tail, but it does not become much smaller for about another third of the whole length, when 'the small' or tail commences; and at this point also, on the back, is a large pyramidal prominence called 'the hump,' from which a series of smaller processes run half way down the 'small' or tail, constituting what the whalers term the 'ridge.' The body then contracts so much as to become finally not thicker than that of a man, and terminates by expanding on the sides into the 'flukes' or tail, forming a large triangular horizontal fin with a slight notch or depression posteriorly between the flukes, which are about 6 or 8 feet in length, and from 12 to 14 feet in breadth in the largest males or 'bulls.' The chest and belly are narrower than the broadest part of the back, and taper off evenly towards the tail; the depth of the head and body is, in all parts except the tail, greater than the width. The head, viewed in front, presents a broad somewhat flattened surface, rounded and contracted above, considerably expanded on the sides, and gradually contracted below, resembling in some degree the cutwater of a ship. The slit of the single blowing-hole or nostril is about 12 inches in length. In the right side of the nose is the 'case,' a cavity for the purpose of secreting and containing an oily fluid, which after death concretes into a granulated yellowish substance: this is the Spermaceti. In the case of a large whale there is not unfrequently a ton, or more than ten barrels of spermaceti. Beneath the case and nostril is the elastic 'junk,' formed of dense cellular tissue, strengthened by strong tendinous fibres, and infiltrated with very fine sperm-oil and spermaceti. The mouth extends nearly the whole length of the head. Both the jaws, especially the lower, are contracted in front to a very narrow point; and when the mouth is closed the lower jaw is received within a sort of cartilaginous lip, or projection of the upper one: but principally in front; for, farther back at the sides, and towards the angle of the mouth, both jaws are furnished with tolerably well-developed lips. The tongue is small and white. The throat is capacious enough to give passage to the body of a man, presenting a strong contrast to the contracted gullet of the Greenland Whale. Throughout, the mouth is lined with a pearly white membrane. The eyes are small in proportion to the size of the animal, and are furnished with eyelids, the lower of which is most moveable. At a short distance behind the eyes are the external openings of the ears, sufficiently large to admit a small quill. Not far from the posterior angle of the mouth are the swimming-paws or fins, which are not much used in progression, but probably more as balances, and occasionally in supporting the young.

Mr. Beale gives the following as the dimensions of a Sperm-Whale of the largest size, or about 84 feet in length:—Depth of head from 8 to 9 feet; breadth from 5 to 6 feet; depth of body seldom exceeding 12 or 14 feet; circumference seldom exceeding 36 feet; swimming-paws about 6 feet long and 3 feet broad.

The skin is smooth, but occasionally in old whales wrinkled. The general colour is very dark, deepest on the upper part of the head, back, and flukes, in which situation it is sometimes black; on the sides it gradually assumes a lighter tint, and on the breast becomes silvery-gray. In different individuals there is however every variety of shade, and some are piebald. Old 'bulls' have generally a portion of gray on the nose, immediately above the fore-part of the upper jaw, when they are said to be 'gray-headed.' The 'black skin' in young whales is about three-eighths of an inch thick; in old ones it is not more than one-eighth. Immediately beneath the black skin is the blubber or fat, termed the 'blanket,' of a light yellowish colour, producing when melted the sperm-oil.

The bulk of the head is, as we have seen, made up of a membranous 'case,' containing a thin oil of much less specific gravity than water; below which again is the 'junk,' which, although heavier than the spermaceti, is still lighter than the element in which the whale moves; consequently, observes Mr. Beale, the head taken as a whole is lighter specifically than any other part of the body, and will always have a tendency to rise at least so far above the surface as to elevate the nostril or blow-hole sufficiently for all purposes of respiration; and more than this, a very slight effort on the part of the whale would only be necessary to raise the whole of the anterior flat surface of the nose out of the water. At very regular intervals of time the snout emerges, and from the extremity of the nose the spout is thrown up, and at a distance appears thick, low, bushy, and white. It is formed of the expired air forcibly ejected through the blow-hole, and acquires its white colour from minute particles of water previously lodged in the chink or fissure of the nostril, and also from the condensation of the aqueous vapour thrown off by the lungs. The spout, says Mr. Beale in continuation, is projected at an angle of 136 degrees, in a slow and continuous manner for about three minutes, and may be seen from the mast-head in favourable weather at the distance of four or five miles. When the whale is alarmed, or 'gallied,' the spout is thrown much higher with great rapidity, and differs much from its usual appearance. Immediately after each spout the nose sinks beneath the water, scarcely a second intervening for the act of inspiration, which must consequently be performed very quickly, the air rushing into the chest with astonishing velocity; there is however no sound caused by inspiration, and very little by expiration in this species: in short, nothing of that loud noise called the 'drawback' in the Finback and other whales. Ten seconds is occupied by a large bull sperm whale in making one inspiration and one expiration: during six of these the nostril is beneath the water. At each breathing-time the whale makes from 60 to 70 expirations, and remains therefore at the surface 10 or 11 minutes. When the breathing-time is over, or, as the whalers term it, he has had his 'spoutings out,' the head sinks slowly, the 'small,' or the part between the 'hump' and 'flukes,' appears above the water, curved, with the convexity upwards; the flukes are then lifted high into the air, and the animal having assumed a straight position, descends perpendicularly to an unknown depth. This last act is called 'peaking the flukes,' and those who are on the look-out call loudly when they see it—'there goes flukes.' The whale continues thus hidden beneath the surface for one hour and ten minutes; some will remain one hour and twenty minutes, and others only for one hour; but these, Mr. Beale says, are rare exceptions. A seventh of the time of this whale is, Mr. Beale makes out, consumed in respiration.

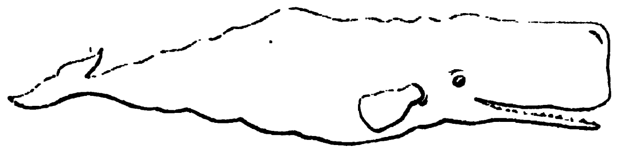
Small fishes are occasionally swallowed in quantities by this whale, and one has been known to eject from its stomach a fish as large as a moderate-sized salmon; but the principal food of the Sperm-Whale appears to consist of squids or cuttle-fishes. [SEPIADÆ.]

This species is gregarious; and the herds called 'schools' are of two kinds, one consisting of females, the other of young males not fully grown. Mr. Beale has seen as many as 500 or 600 in one 'school.' With each female 'school' are from one to three large 'bulls' or 'school-masters,' as they are termed by the whalers. The full-grown males almost always go alone in search of food: they are when alone very incautious and easily killed. It is the smaller, or 'forty-barrel bull,' as he is called, that makes the most desperate resistance. A large whale will yield 80 barrels of oil, and sometimes 100.

Mr. Beale states that the female is smaller than the male, and that she breeds at all seasons, producing generally only one at a time, but sometimes two. Nothing certain appears to be known as to the period of gestation, but F. Cuvier supposes it to be ten months. A fœtal Cachalot, dissected by Mr. Bennett, was 14 feet long and 6 feet in circumference, deep black, mottled with white spots. Its position in the womb was that of a bent bow. According to F. Cuvier, the two brought forth by the Stranded Whale near D'Audierne, were 10 or 11 feet long; and Captain Colnett states that the young Sperm-Whales which he saw in great numbers off the Galapagos Islands were not larger than a small Porpesse. Mr. Beale's own observations coincided with those of Mr. Bennett.

For many other habits of this whale, such as 'breaching,' or leaping clear out of the water and falling back again on its side, so that the breach may be seen in a clear day from the mast-head at a distance of six miles; 'going head out,' a mode of progression which enables it to attain 10 or 12 miles an hour, which Mr. Beale believes to be its greatest velocity; 'lob tailing,' or lashing the water with its tail; and the vivid descriptions of the dangers and hair-breadth escapes attending its capture, we must refer to Mr. Beale's book, which every one who is anxious for information on this subject should read.

This animal is an inhabitant of the north; it has however been found on the coasts of America, Japan, New Guinea, and Timor. It has been frequently stranded on the British Islands. Twelve males were caught at Walderwich on the Suffolk coast in 1788. There is a skeleton of an adult at Burton-Constable Castle, near Hull, in Yorkshire. It has been taken also near Teignmouth, in Whitstable Bay, and in the Frith of Forth.



The Spermaceti Whale (*Catodon macrocephalus*). Beale.

C. Colneti, the Mexican Sperm-Whale, is an inhabitant of the North Pacific, the South Seas, and equatorial oceans, and often referred to the last species.

C. polycyphus, the South Sea Sperm-Whale, is found in the Southern Ocean, and is also spoken of as the Cachalot, or Sperm-Whale.

Kogia is the generic name given by Dr. J. E. Gray to a form of whale with a shorter head, which has been taken at the Cape of Good Hope. It has been sometimes regarded as the young of the Sperm-Whale.

K. breviceps, the Short-Headed Whale of Gray, is the only species, and has been described from a single skull in the Paris Museum.

Physeter is the generic term applied by Linnæus and many subsequent writers to the Sperm-Whale, but it was originally applied by Artedi to the Black Fish, to which Dr. J. E. Gray has restored it in the 'British Museum Catalogue.'

P. Tursio, the Black Fish of Gray, is the *Physeter microps* and *P. Tursio* of Artedi, and probably the *Delphinus globiceps* or *D. Grampus* of Cuvier. It is of a black colour. The teeth are from 11 to 22 on each side. It is an inhabitant of the North Sea. Two specimens, 52 feet in length, have been taken off the coasts of Scotland, and were described by Sibbald. Of one of the specimens Sibbald observes, "The size of the cranium may be estimated by the fact that four men were seen inside it at one time extracting the brain, which contained several cells or alveoli, like those which bees keep their honey in, and in these were rounded masses of a white substance, which upon examination were proved to b[illegible]m. Some of this substance was also found externally on the he[illegible] some parts to the thickness of two feet."

The family of DELPHINIDÆ, or Dolphins, are more numerous than those of the other *Cetacea*. They are distinguished from the last family by the smaller and more proportionate head; and in those species which have lost their upper teeth at an early age, by there being no regular pits in the gums of the upper jaw for the reception of the teeth of the lower one; and also by the hinder part of the skull not being deeply concave, and surrounded on the sides and behind by a high ridge.

The following is a synopsis of the genera and sub-families of this extensive family:—

A. Jaws tapering; the symphysis of the lower jaw short, not half the length of the jaw. Dorsal fin generally distinct; pectoral fin ovate, acute. Marine.

a. Upper jaw toothless; lower jaw with only one or two teeth (which are often hidden in the gums) on each side. Beak of the skull keeled on each side, the keel being sometimes large, and forming a kind of reflexed wing on each side; head with a short beak. *Hyperoodontina.*

1. *Hyperoodon.* The beak of the upper jaw with a large erect wing-like expansion in front of the blowers; lower jaw with two rudimentary teeth in front.

2. *Ziphius.* Beak of upper jaw keeled on each side; lower jaw broad, bent down in front with large compressed teeth in the middle of each side.

3. *Delphinorhynchus.* Beak of upper jaw keeled on each side; lower jaw nearly straight, with two or three small rudimentary conical teeth in the middle of each side.

b. Upper and lower jaw with few or deciduous teeth. Wings of the maxillary bones expanded and shelving downwards. The beak short, deflexed. Forehead convex. Head rounded, without any beak. *Monoceratina.*

* Lower jaw toothless.

4. *Monodon.* Upper jaw of males with one or two very long projecting spirally-twisted tusks. Dorsal fin none.

** Upper and lower jaw with conical, early deciduous teeth.

5. *Beluga.* Dorsal fin none.

*** Upper and lower jaw with compressed permanent teeth.

6. *Neomeris.* Dorsal none.

7. *Phocæna.* Dorsal triangular, in the middle of the back.

c. Upper and lower jaw with many teeth, rarely deciduous with age. Wings of the jaw-bone horizontally produced over the orbits. *Delphinina.*

* Head rounded in front, not beaked. Nose of skull scarcely so long as the brain-cavity. Dorsal distinct.

8. *Grampus.* Teeth conical, truncated, early deciduous. Intermaxillaries broad. Pectoral ovate.

9. *Globiocephalus.* Teeth conical, deciduous when old. Intermaxillaries very broad. Pectorals narrow, linear.

10. *Orca.* Teeth conical, acute, permanent. Intermaxillaries moderate. Pectorals ovate.

** Head beaked. Nose of skull as long as or longer than brain-cavity.

11. *Lagenorhynchus.* Head shelving in front. Dorsal rather posterior. Nose of skull depressed, expanded.

12. *Delphinapterus.* Head rather convex in front. Dorsal none. Nose of skull rather depressed, convex above.

13. *Delphinus.* Head rather convex in front. Dorsal medial. Nose of skull rather depressed, convex above.

14. *Steno.* Head rather convex in front. Dorsal medial. Nose of skull compressed, higher than broad; symphysis of lower jaw rather elongate.

15. *Pontoporia.* Head rather convex in front. Dorsal medial. Nose of skull rather compressed; high symphysis of lower jaw very long.

B. Jaws much compressed; symphysis of the lower jaw very long. Dorsal none. Teeth in both jaws. Fluviatile.

d. Skull with the maxillary bones simple, expanded over the orbit. Teeth conical. Paddles ovate or oblong. *Iniana.*

16. *Inia.* Teeth rugose; the hinder ones with a rounded tubercle on the inner side.

e. Skull with the maxilliary bones bent up in front of the blowers, and forming a vault. The teeth compressed. The paddles fan-shaped, truncated at the end. *Platanistina.*

17. *Platanista.*

Hyperoodon Butzkopf, the Bottle-Head. It is the Flounder's Head of Dale, in his 'History of Harwich,' where it has been taken. Pennant calls it the Beaked Whale. It inhabits the North Sea.

H. rostratum, the Beaked Hyperoodon, is an inhabitant of the North Sea. It differs from the last species in having the dorsal fin behind the middle of the back. It has been taken in the Thames and the Humber, and skeletons exist in the museums of Edinburgh, Bristol, and Liverpool.

Two other species of Hyperoodon are described by Dr. J. E. Gray, *H. Desmarestii* and *H. latifrons*. The latter is a native of the North Sea, and has been taken on the coast of Lancashire.

Ziphius Sowerbiensis is the *Physeter bidens* of Sowerby, the *Diodon bidens* of Bell. The head of a specimen caught in Scotland is now in the museum at Oxford. Dr. Gray observes that "it belongs to the genus *Ziphius* of Cuvier, before only known in the fossil state; and the examination of the skull has proved the accuracy of these determinations."

Z. Sechellensis, named from a skull in the museum at Paris brought from the Sechelles.

Delphinorhynchus micropterus was first described by De Blainville. It inhabits the seas of the coasts of Europe.

Monodon monoceros, the Narwhal, Unicorn, or Unicorn-Whale. It is the *Monodon microcephalus* and *Narwhalus Andersonianus* of Desmarest. When young it is black, but when old it is whitish marbled. Although it has sometimes two tusks, it has more frequently one, from which it derives its name of Unicorn. It inhabits the Northern Ocean, and is not unfrequent on the coast of Scotland.

The use of the tusk has been a matter for discussion. Dr. Scoresby has expressed an opinion that as the end of the tusk is smooth and clean, while the rest of it is rough and dirty, and as a broken tusk was found rubbed and rounded, it may be used to pierce thin ice for the purpose of enabling the animal to respire without the necessity of retreating into open water. Again, he states that his father sent him the contents of a Narwhal's stomach, consisting of several half-digested fishes, with others of which the bones only remained. There were the remains of a cuttle-fish, part of the spine of a flat-fish, probably a small turbot, and a skate almost entire. The last was two feet three inches in length, and one foot eight inches in breadth, comprising the bones of the head, back, and tail, the side-fins, and considerable portions of the muscular substance. It appears, he observes, remarkable that the Narwhal, an animal without teeth, with a small mouth and stiff lips, should be able to catch and swallow so large a fish as a skate, the breadth of which is nearly three times as great as the width of its own mouth. As the animal in which these remains were found had a tusk of seven feet, Dr. Scoresby apprehended that this instrument had been employed in the capture of the fishes on which it had recently fed. It seemed probable to him that the skates had been pierced with the horn and killed before they were devoured; otherwise, he observes, it is difficult to imagine how the Narwhal could have swallowed them, or how a fish of any activity would have permitted itself to be taken, and sucked down the throat of a smooth-mouthed animal without teeth to detain and compre[illegible]

The Narwhal (*Monodon monoceros*).

Narwhals swim with great swiftness. When at the surface for respiration they blow repeatedly with considerable force, and then frequently lie motionless for several minutes with their back and head just above water. Dr. Scoresby describes them as often sporting about his ship, sometimes in bands of about twenty together, often elevating their long tusks and crossing them with each other as if they were fencing. They often uttered a very unusual sound resembling the gurgling of water in the throat, which Dr. Scoresby thinks produced it, as it only occurred when they reared their tusks, with the front of the head and mouth out of the water. Several of them followed the ship, seeming to be attracted by curiosity. As the water was perfectly transparent, they could be seen descending to the keel and playing about the rudder for a considerable time. Sir Jŏseph Banks stated to Dr. Fleming, who has published a very interesting account of one in the 'Wernerian Transactions,' that a Narwhal stranded on the Lincolnshire coast was found with the whole of its body buried in the mud of the beach, and seemed safely and securely waiting the return of the tide.

The blubber of the Narwhal yields a very superior oil, which, as well as the flesh, is considered a dainty by the Greenlander. It is regarded as the herald of the Mysticete, in whose neighbourhood the former is said generally to be found—perhaps from partaking of the same food. When harpooned it swiftly dives to about 200 fathoms, and on its return to the surface is killed by lances. The Greenlander drives them to fissures in the ice, where they come up to respire, and kills them with harpoons, &c. The ivory of the tusk is considered superior to that of the elephant; it is very dense and hard, very white, is not subject to become yellow, and is susceptible of a high polish. They formerly brought a high price, and many virtues were attributed to them: they still form a valuable article in commerce. The celebrated throne of the Danish kings is stated to be made of the tusks of this animal.

Beluga Catodon, the Northern Beluga. It is the *Cetus bipinnis* of Brisson; *Physeter Catodon* of Linnæus; *Delphinus leucas* of Pallas; *Catodon Sibbaldii* of Fleming; the Beluga, Round-Headed Cachalot, Small Catodon, of English writers; the White Whale, and White Fish, of whalers; and the *Albus Piscis Cetaceus* of Ray. It is known by its white colour. When young however it is black. It is an inhabitant of the North Sea, and has been taken in Scotland. We are informed by Mr. Whittle of the dockyard, Chatham, that one made its appearance in the waters of the Medway in the spring of 1846, advancing daily with the flow of the tide for a month as high as Rochester bridge. It was at last shot near Upnor Castle. It measured 13 feet 1 inch, and was all over of a most delicate primrose yellow colour. The dental formula was $\frac{10-10}{8-8}$.

One of these dolphins haunted the Frith of Forth in the summer of 1815 for nearly three months, passing almost daily upwards, and again retiring with the flood and ebb. It was supposed to be in pursuit of salmon, and after many unsuccessful attempts the salmon-fishers killed it with fire-arms and spears. Mr. Bald of Alloa bought it, and sent it to Professor Jameson: it is now in the Edinburgh Museum, and formed the subject of the interesting observations of Dr. Barclay and Mr. Neil in the 'Transactions of the Wernerian Society.'

Mr. Neil remarks that the shape of this animal is very symmetrical, suggesting the idea of perfect adaptation to rapid progression in the water. "Its head," he observes, "is small and lengthened, and over the forehead there is a thick round cushion of flesh and fat: the body continues to swell as far as the large thick oval flippers, and from that point gradually diminishes to the setting on of the tail, which is powerful, and described as bent under the body in swimming, and propelling the animal with the velocity of an arrow."

In the specimen examined by Mr. Neil the teeth were $\frac{9-9}{6-6}$.

The higher and arctic latitudes appear to be the chosen haunts of the *Beluga*. They abound in Hudson's Bay, Davis's Straits, and on parts of the southern coasts of Asia and America, where they ascend the large rivers. Steller noticed them at Kamtchatka; and in Charlevoix's time they were numerous in the Gulf of St. Lawrence, going with the tide as high as Quebec. Disco Island in Greenland is said to abound with them, nor are they scarce at Spitzbergen. Scoresby did not see them lower than Jan Mayen's Land; he seldom observed them among the ice, but where the water was clearest and smoothest. They are described as not at all shy, but often following the ships, tumbling about the boats in herds of forty or fifty, bespangling the surface with their brilliant whiteness. The whale-fisher seldom disturbs these beautiful creatures, for they are not only difficult to strike on account of their activity, but when stricken the harpoon frequently draws, and if it holds the capture is but of little value. Sir Charles Giesecke speaks of their regular annual visits about November to the west coast of Greenland, where they become a seasonable supply to the natives when other provisions fall short. They arrive in herds with stormy weather and south-west winds, and are taken with harpoons and strong nets. Cod, haddock, flounders, &c., are said to be the usual food of the *Beluga*.

The White Whale (*Beluga Catodon*).

The oil is reported to be of the best, whitest, and finest quality, and of their skins a sort of morocco leather is said to be made, which, though thin, will resist a musket-ball. The internal membranes are used for windows and bed-curtains, and the sinews for thread. The flesh, it is asserted, resembles beef, though somewhat oily. Hans Egede describes both it and the fat as having no bad taste "when it is marinated with vinegar and salt;" and says that it is then as well-flavoured as any pork whatever. He declares the fins also and the tail "pickled or sauced" to be very good eating; so that, according to Hans, "he is very good cheer."

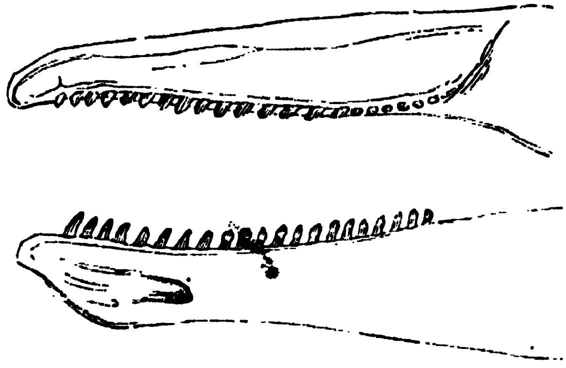
B. Kingii is the representative of the last species in the Southern Hemisphere. It has been taken off the coasts of Australia.

Neomeris Phocænoides is the name given by Dr. J. E. Gray to a species of Dolphin found [illegible] Indian Ocean, the *Delphinus melas* of Temminck.

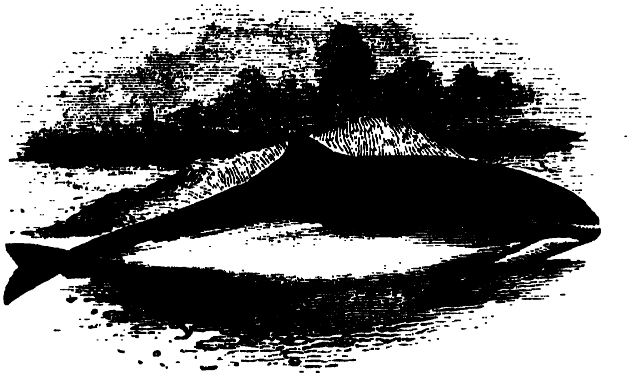
Phocæna communis, the Common Porpoise, or Porpesse. It is the *Phocæna Rondeletii* of Willughby, *Delphinus Phocæna* of Linnæus. It appears to be the Φώκαινα of Aristotle ('Hist. Anim.' vi. 12). Pennant supposes it to be the *Tursio* of Pliny ('Nat. Hist.' ix. 9), which, according to the Roman naturalist, bears some likeness to the Dolphins, of which he relates so many anecdotes illustrative of their affection for man in the preceding chapter. It is the Porco Pesce of the Italians (whence probably the English name Porpesse); Marsouin of the French; Marsuin and Tumblare of the Swedes; Meerschwein of the Germans; and Llamhidydd of the ancient British. It is the most common of all the *Cetacea* on the British coasts. It is black all over.

The following is its dental formula:—Molars, $\frac{40 \text{ to } 46}{40 \text{ to } 46} = 80 \text{ to } 92$.

Porpesses swim in shoals, and drive the mackerel, herrings, and salmon before them, pursuing them up the bays "with the same eagerness," says Pennant, "as a pack of dogs does a hare. In some places they almost darken the sea as they rise above water to take breath: they not only seek for prey near the surface, but often descend to the bottom in search of sand-eels and sea-worms, which they root out of the sand with their noses, in the same manner as the hogs do in the field for their food." In fine weather they leap, roll, and tumble in the manner so well known, principally in the spring and summer, which is supposed to be their rutting season. They go up the rivers in pursuit of the salmon, to which they are a deadly enemy, and other fish; and have been seen high in the Loire, Charente, and Seine in France. It has been remarked that when the Porpesses are gambolling in the spring and summer, they appear heedless and blind to all danger and risk, which, as their brain is highly developed, strengthens the supposition that they are at such times actuated by the sexual impulse to an extent that lessens their usual wariness. On the 23rd May, 1842, we saw about 10 a.m. two rolling and sporting a little above London Bridge, towards the Surrey shore. They seemed to disregard the numerous steam-vessels which were constantly passing, and to pay no attention to the wherries, some of which went close to them. The man on the look-out in the steamer from whose deck we watched them said that they had been seen between five and six that morning near Southwark Bridge, and that one of them had been hooked with a boat-hook, but had got away. It was blowing fresh from the south-west, and the tide was running up: the time for high water at London Bridge that day being 45 minutes after 12.



Teeth of Porpesse (*Phocæna communis*). F. Cuvier.



The Porpoise, or Porpesse (*Phocæna communis*).

The oil procured from the fat surrounding the body of the Porpoise is of the purest kind, and the skin when carefully tanned and dressed is used for wearing apparel, and for coverings for carriages. The shoals of these creatures on the west coast of Ireland are immense, and might be well worth the attention of the neighbouring population if furnished with boats and proper implements for their capture, and conversion to economic purposes. As an article of food the flesh was anciently esteemed, and considered worthy of the tables of the great. Receipts for dressing it appear in the 'Forme of Cury,' compiled (circ. 1390) by the master cooks of King Richard II. It appears to have been served in 'furmente,' in broth, and roasted, and was evidently used both fresh and salted. Several of them were on the board at the great feast holden at the 'intronazation' of George Nevell, archbishop of York, in the reign of Edward IV. In Henry VIII.'s time it continued to be a royal dish, and was in fashion in the reign of Elizabeth. It appears to have been in those days generally presented as a roast with a sauce made of fine white bread-crumbs, mixed with vinegar and sugar. The Common Dolphin (*Delphinus delphis*) was then considered so great a delicacy that, according to Dr. Caius, one which was taken in his day was thought a present worthy of the duke of Norfolk, who distributed it amongst his friends: it was roasted and dressed with the porpesse-sauce last above mentioned. At a later period the Porpesse kept its ground on the table of Roman Catholics on fish-days and during Lent. Nor have modern navigators found it undesirable food. Captain Colnett's people, who fell in with numbers of them off the Mexican coast, mixed their flesh with their salt-pork—making excellent sausages, which formed their ordinary food. Captain Basil Hall speaks with some unction of a dish of porpesse-cutlets, well separated from the investing lard and blubber, which was served at his table with such happy effect that the dish left his cabin empty.

The flesh of the porpesse is the Greenlander's great dainty, and he quaffs its oil as the most delicious of draughts.

Grampus Cuvieri is the *Delphinus griseus* of Cuvier; *Phocæna grisea* of Lesson. It is an inhabitant of the North Sea, and has been taken off the coast of France, and also off the Isle of Wight.

G. Rissoanus. A specimen was taken at Nice, and described by Risso.

G. Richardsonii. Described by Dr. Gray in the Zoology of the Erebus and Terror.

G. Sakamata. Described by Schlegel in 'Fauna Japonica' as *Sakamata Kuzira.* It has been found off the coasts of Japan.

Globiocephalus Svineval, the Pilot-Whale, also known to sailors as the Black Whale, Howling Whale, Social Whale, and Bottle-Head. It is the *Delphinus globiceps* of Cuvier, the Narwal Edente and Petit Cachalot of the French. It is of a black colour, with a white streak from throat to vent. It is a native of the North Sea, and has been taken off the coast of Scotland. A skull in the British Museum measures 28 inches in length.

G. intermedius is the Black Fish of American sailors. It inhabits the coasts of North America.

G. affinis, the Smaller Pilot-Whale. Its locality is unknown. A specimen exists in the museum of the College of Surgeons. It is the *Delphinus melas* of Owen.

G. Sieboldii is a native of the coasts of Japan, where it is called Naiso-Gota.

G. macrorhynchus is the Black Fish of the South Sea whalers. It inhabits the South Seas.

Orca Gladiator, the Killer. It is the *Delphinus Orca* of Linnæus, *Grampus* of Hunter, *Delphinus Grampus,* and Large Grampus, of Owen. It inhabits the North Sea, and has been taken on various parts of the British coasts. There is the skull of one in the Hunterian Collection at the Royal College of Surgeons which was killed at Greenwich in 1793.

O. crassidens is a fossil species. It is described by Professor Owen in the 'British Mammals and Birds' under the name of *Phocæna crassidens.* A skull was found in the fens of Lincolnshire in 1843.

O. Capensis, the Cape Killer, is the *Delphinus globiceps* of Owen. It inhabits the Southern Pacific Ocean.

O. intermedia is a smaller species, described by Dr. Gray in the Zoology of the Erebus and Terror.

Lagenorhynchus leucopleurus, the White-Sided Bottlenose. It is the *Delphinus Tursio* of Knox. It is a native of the North Sea. The skeleton of a specimen taken in the Orkneys is in the museum of the University of Edinburgh.

L. albirostris, White-Beaked Bottlenose. A specimen was taken off the coast of Norfolk in 1846.

L. Electra, the Electra. Described by Dr. Gray in the Zoology of the Erebus and Terror.

L. cæruleo albus. It is an inhabitant of the east coast of South America—Rio de la Plata.

L. Asia. Described by Dr. Gray in the Zoology of the Erebus and Terror. Locality unknown.

L. acutus. It inhabits the North Seas—Faroe Islands.

L. clanculus. Described by Dr. Gray from a skull brought from the Pacific Ocean.

L. Thicolea. Described by Dr. Gray from a skull brought from the west coast of North America.

Delphinapterus Peronii. It is the Right Whale-Porpoise of the whalers. It is black, with the exception of the beak, pectoral fins, and under part of the body, which are white. It is found on the Brazil Bank, off New Guinea, and in the higher southern latitudes. There are two skulls in the museum at Paris. They live in large shoals, and the flesh is esteemed a delicacy.

D. borealis. It inhabits the North Pacific Ocean. It has been described by Peale in the United States Exploring Expedition.

Delphinus. The English name for this genus is Dolphin, but as Dr. J. E. Gray observes:—"Most maritime persons call these animals Bottlenoses, Bottleheads, Flounderheads, Grampuses, Porpoises, Porpesses or Porpusses, sometimes adding Whale to the name. They generally confine the name of Dolphin (most used by landsmen) to the Scomberoid Fish (*Coryphæna*), which changes colour in dying." [CORYPHÆNA.] We subjoin a synopsis of the characters with the localities of the species of this large genus:—

A. Head shortly beaked; nose of skull moderate; triangle or hinder part of beak elongate, produced before the teeth-line; palate flat. Teeth $\frac{24-40}{24-40}$.

† Beak scarcely produced; nose of skull rather depressed, scarcely longer than the brain cavity. Teeth $\frac{24-30}{24-30}$.

1. *Delphinus Heavisidii,* the Hastated Dolphin, inhabits the South Sea—Cape of Good Hope.

2. *D. obscurus,* Dusky Dolphin, inhabits the Southern Ocean—Cape.

3. *D. compressicauda,* the Compressed-Tailed Dolphin, inhabits 4° S. lat., 24° W. long.

†† Beak short; nose of skull rather thick, conical, convex above, half as long as the head.

* Beak of skull rather thick and rather swollen on the sides.

4. *D. Tursio,* Bottlenose Dolphin, inhabits the North Sea.

5. *D. Abusalam* inhabits the Red Sea.
6. *D. Eutropia* inhabits the Pacific Ocean—Chili.
7. *D. Eurynome* inhabits the North Sea.

** Beak of skull rather thick, conical, evenly tapering.

8. *D. Metis*, the Metis. Locality unknown.
9. *D. Cymodoce*, the Cymodoce. Locality not known.

*** Beak of skull slender, cylindrical.

10. *D. Doris*. The Doris. Inhabits —— ?
11. *D. frenatus*, the Bridled Dolphin, inhabits Cape de Verds.

B. Head longly beaked. Nose of skull slender, light, rather depressed, especially in front, much longer than the head. Teeth $\frac{40-60}{40-60}$.

* Skull flattened behind; triangle to the teeth line. Palate flat, not grooved on the side.

12. *D. Clymene*. Locality unknown.
13. *D. Styx*, the Styx, inhabits West Africa.
14. *D. Euphrosyne*, the Euphrosyne, inhabits the North Sea.
15. *D. Alope*, the Alope. Locality unknown.

** Skull roundish; triangle just to the teeth line. Palate with a deep groove on each side, and a high central ridge behind.

† Beak moderate, 1½ the length of the brain cavity. Teeth $\frac{45}{45}$ or $\frac{50}{50}$.

16. *D. Delphis*, the Dolphin, inhabits the North Sea, Atlantic Ocean. Has been taken on the English coast.
17. *D. Janira*, the Janira, inhabits Newfoundland.
18. *D. Novæ Zealandiæ*, the New Zealand Dolphin, inhabits New Zealand and Cape Gable.
19. *D. Forsteri*, Forster's Dolphin, inhabits the Pacific Ocean between New Calcdonia and Norfolk Island.
20. *D. Sao* inhabits Madagascar.

†† Beak of skull twice as long as the brain cavity. Teeth $\frac{55-60}{55-60}$.

21. *D. longirostris*, the Cape Dolphin, inhabits the Southern Ocean. —Cape of Good Hope.

*** Skull round; triangle not reaching to the teeth line. Palate convex, with a very concave line on the hinder part of each side. Beak twice as long as the head. Teeth $\frac{50}{50}$.

22. *D. microps*, the Small-Headed Dolphin, inhabits the coasts of Brazil.

Steno Malayanus. It is the Delphin à Ventre Roux of the Paris Museum, *Delphinus plumbeus* of Cuvier. It is a native of the Indian Ocean.

S. frontatus. It inhabits the Indian Ocean and the Pacific.

S. compressus. Described by Gray in the Zoology of the Erebus and Terror.

S. attenuatus. Found at Cape Horn.

S. fuscus. Described by Gray in the Zoology of the Erebus and Terror. A fœtus was brought from Cuba by Mr. M'Leay.

S. rostratus. It inhabits the North Sea, and has been taken at Holland and at Brest.

Pontoporia Blainvillii. It has been found off Monte Video. A skull is in the museum at Paris. It is described by Freminville as *Delphinus Blainvillii.*

Inia Geoffroyii. A native of Upper Peru or Bolivia—River Moxos. "The specimen," says Gray, "in the Paris Museum, which Desmarest described as *Delphinus Geffroyii*, is evidently this species."

Platanista Gangetica. It is the Sou Sou of India, the Susu of Buffon, the *Platanista* of Pliny, Dauphine du Gange of Cuvier, *Delphinus Shawensis* of Blainville.

The family Manatidæ includes a number of animals, which, although usually referred to *Cetacea*, have relations which have induced some zoologists to propose that they should be placed amongst other orders of *Mammalia*. They differ from the animals we have already considered in being entirely vegetable feeders, and are comprised in the division of Phytophagous Cetaceans of the two Cuviers.

It is not indeed surprising that they should so long have been confounded with the Cetaceans; for their general appearance and horizontal tail, joined to the difficulty of associating them either with the Seals or the Walruses, notwithstanding their aquatic habits, led naturally to their being placed in the same order with the true Zoophagous Whales. But with external form almost all resemblance ceases; and when these Phytophagous Mammals are, as they ought to be, referred to a separate group, there will not be, so far as discovery has hitherto gone, any such animal as a Phytophagous Whale.

"The short and thick neck, fin-like fore legs, want of hind legs, caudal tegumentary fin, smooth, naked, and almost hairless integument, are all modifications of external form by which the Dugongs and Manatees are adapted to play their part in the water: but the kind of part," says Professor Owen, "which they are to play in that element depends on organic characters which mainly, if not exclusively, reveal their true affinities. Now we have seen that the whole of the internal structure in the Herbivorous *Cetacea* differs as widely from that of the Carnivorous *Cetacea* as do their habits: that the amount of variation is as great as well could be in animals of the same class existing in the same great deep. The junction of the Dugongs and Manatees with the true Whales cannot therefore be admitted in a distribution of animals according to their organisation. With much superficial resemblance they have little real or organic resemblance to the Walrus, which exhibits an extreme modification of the amphibious carnivorous type. I conclude therefore that the Dugong and its congeners must either form a group apart, or be joined, as in the classification of M. de Blainville, with the Pachyderms, with which the Herbivorous *Cetacea* have the nearest affinities, and to which they seem to have been more immediately linked by the now lost genus *Dinotherium*."

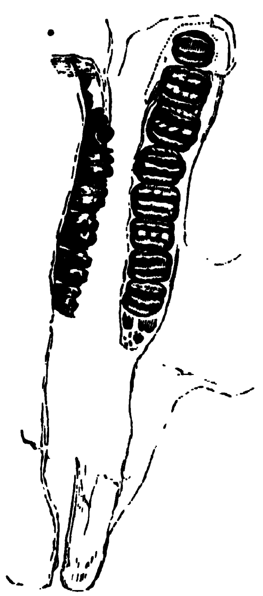
The following is a synopsis of the genera:—

1. *Manatus*. Tail rounded. Grinders, $\frac{9}{9}$ or $\frac{6}{6}$, tubercular.
2. *Halicore*. Tail forked. Grinders, $\frac{3}{3}$; flat-tipped; upper cutting-teeth produced, tusk-like.

Rytina. Tail forked. Grinders none.

Manatus australis, the Manatee. This is the Lamantin of Buffon; *Trichechus Manatus* of Linnæus; *Manatus Americanus* of Desmarest; Manate del'Orenoque of Humboldt; Lamantin d'Amérique of Cuvier. The terms Manatee and Lamantin are indifferently applied to this and the following species. The present species is of a gray-black colour, and is an inhabitant of the warmer parts of America and its islands.

Cuvier describes the Manatees as having an oblong body terminated by an elongated oval fin; eight molar teeth in each jaw, with a square crown marked by two transverse ridges; neither incisors nor canines in the adult; but in the very young ones two small pointed teeth are found in the intermaxillary bones, which disappear early. The vestiges of nails are observable on the edges of their flippers, which they use dexterously enough in creeping and carrying their young. This has caused these organs to be compared to hands; whence their name Manati, or Manatee.



Teeth of Manatee (*Manatus australis*).

The mammæ of the Manatees and Dugongs are pectoral, and this conformation, joined to the adroit use of their flippers (whose five fingers can be easily distinguished through the investing membranes, four of them being terminated by nails) in progression, nursing their young, &c., have caused them, when seen at a distance with the anterior part of their body out of the water, to be taken for some creature approaching to human shape so nearly (especially as their muzzle is thick set with hairs, giving somewhat of the effect of human hair or a beard), that there can be little doubt that not a few of the tales of Mermen and Mermaids have had their origin with these animals, as well as with Seals and Walruses. Thus the Portuguese and Spaniards give the Manatee a denomination which signifies Woman-Fish; and the Dutch call the Dugong Baardmannetje, or Little Bearded Man. A very little imagination and a memory for only the marvellous portion of the appearance sufficed doubtless to complete the metamorphosis of this half woman or man, half-fish, into a Siren, a Mermaid, or a Merman; and the wild recital of the voyager was treasured up by such writers as Maillet, Lachesnaye-des-Bois, Sachs, Valentyn, and others, who, as Cuvier well observes, have displayed more learning than judgment.

This and the other species of Manatees are called by English sailors the Sea-Cow and the Woman-Fish, and by the French Bœuf Marin and Vache Marine.

The Manatees are gregarious, and generally go in troops. The young are usually placed in the centre of the herd for protection, and on the approach of danger all unite for the common safety. It is alleged that, when one has been struck by a harpoon, its companions will tear out the weapon; and they are so attached to their young that if the calf be taken, the captors are sure of the mother, from the recklessness with which her maternal affection leads her to the place of capture. If the mother be captured, the young follow her to the shore, and fall an easy prey.

The shallow bays of the Antilles and the quiet creeks of the South American rivers, particularly in Guyana and the Brazils, are the favourite haunts of the Manatee. They were formerly abundant at the mouths of the Orinoco and Amazon, ascending many miles, even into their tributaries and the fresh-water lakes. There, their actions are recorded as being similar in some respects to the whales, such as 'breaching,' or leaping to a considerable height out of the water. The food is entirely vegetable, consisting of subaqueous plants and littoral herbs principally.

The mild innoffensive manners of the Manatee, and the unsuspecting nature of the animal, make it an easy prey to the hunter, who pursues it for the sake of the flesh, which all pronounce to be excellent, both fresh and salted. Hernandez compares it to well fatted pork of pleasant flavour. Others compare it, when roasted, to beef or veal in flavour, and state that when salted it makes excellent sea provision.

It is alleged that formerly they were so plentiful within ten or twelve leagues of Cayenne, that a large boat might be filled with them in a single day, when their flesh was sold in the market at about 3*d.* per lb. But the eagerness with which it was purchased soon reduced the numbers, and made them comparatively scarce.

The capture is generally effected by means of the harpoon. At St. Domingo the hunters approached them in a small boat, and struck them with a large harpoon to which a long stout cord was made fast. The stricken animal made violent efforts to escape, carrying with it the harpoon and cord, to the end of which a cork or piece of light wood to serve as a buoy was attached, and indicated the whereabouts of the Manatee. After a while the hunters took hold of the rope and at last drew the exhausted animal on shore, where it was killed. The sport of Manatee-catching, thus conducted, is described as highly exciting, but the boat is sometimes upset by the struggles of the animal in the shoals.

Manatees have reached Europe. The carcass of one which had been long dead, is recorded to have come on shore at Newhaven in the Frith of Forth, in the autumn of 1785; and Duhamel states that one with its cub was thrown on shore near Dieppe.

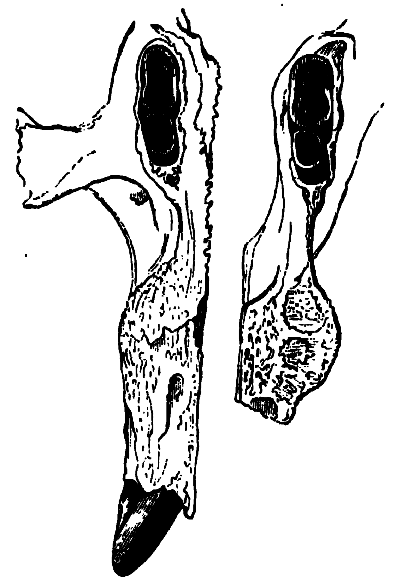
The Manatee (*Manatus australis*).

M. Senegalensis, the Lamantin. This species is a native of the west coast of Africa. It is the *Manatus Senegalensis* of Desmarest; Lamantin of Adanson; Lamantin du Senegal of Daubenton; the Woman-Fish of Purchas; the Round-Tailed Manati of Pennant.

Halicore Dugong, Indian Dugong. It is the *Trichechus Dugong* of Gmelin; *Dugungus Indicus* of Hamilton; Le Dugong des Indes of French writers.

The head of this Dugong is small in proportion to the body, which in general form much resembles that of the Manatee. The large upper lip is thick and obliquely truncated, and the truncated surface, which forms the short and nearly vertical snout, is furnished with soft papillæ and a few bristles. A horny substance covers the lips, the upper of which is very moveable and tumid on the edge; the lower is much smaller, resembling a round or oblong chin. The inside of the cheeks is furnished with strong projecting bristles. The nostrils are situated on the summit of the upper jaw, where it curves downwards, and penetrate obliquely, so that the upper semilunar edge presses upon the lower surface to form a valve capable of being shut at the will of the animal. The eyes are small. The little aperture of the ear is hardly perceptible. The mammæ are placed on the chest, beneath the thick and fleshy flippers or paws, which are rather warty on their anterior edge; but there is no appearance of nails. The tail is broad, and lobated or crescent-shaped. The skin is three-quarters of an inch thick, of a uniform bluish colour, sometimes blotched with white below. Length from 7 to 8 feet.

The attention of Professor Owen was particularly directed to the state of the dentition of the Dugongs of different sexes which he examined, from which it appeared that, as in the Narwhal, the permanent tusks of the female are arrested in their growth, and remain throughout life concealed within the substance of the intermaxillary bones and the alveolar integument. The cavity of the tusks, he states, is in like manner filled up by the secretion of the pulp which retrogrades in the course of its absorption, and hence the tusks are solid, like the corresponding tusks in the female Narwhal, or at least present only a shallow cavity at their expanded and distorted base. He found in one cranium of a male Dugong, in the upper jaw, the deciduous incisors or tusks co-existing with the permanent ones. In the skull of a male which had $\frac{3-3}{2-3}$ molars, the sockets of the deciduous incisors were obliterated, and the points of the permanent ones projected from their sockets. Not more than 20 grinders, 5 on each side of the jaw, appear to be developed in this animal.



Teeth of Dugong (*Halicore Dugong*). F. Cuvier.

"It is obvious," says Professor Owen, "that the different form and condition of the tusks thus observed in the heads of Dugongs of the same size and age, might be regarded as indicating a specific instead of a sexual difference. Dr. Knox inclines to the former opinion; I have however adopted the latter view, not hastily or hypothetically, but as a result of the minute comparison of the forms and proportions of all the crania which have come under my observation."

H. Dugong is an inhabitant of the Indian Ocean.

"The external form of the Dugong," says Professor Owen, "is not so well calculated for moving rapidly through the water as that of the Dolphin and other Carnivorous *Cetacea*, which subsist by a perpetual pursuit of living animals. In these the snout is conical and peculiarly elongated, and in some, as the *Delphinus Gangeticus*, the jaws are produced to an extreme length, so as to give them every advantage in seizing their swift and slippery prey; whilst in the herbiferous Dugong the snout is as remarkable for its obtuse truncate character—a form however which is equally advantageous to it, and well adapted to its habits of browsing upon the *Algæ* and *Fuci* which grow upon the submarine rocks of the Indian seas. As, from the fixed nature of the Dugong's food, the motions of the animal during the time of feeding must relate more immediately to the necessity of coming to the surface to respire, its tail, the principal locomotive organ of ascent and descent, is proportionally greater than in the true *Cetacea*, its breadth being rather more than one-third the length of the whole body. But the most important external differences are seen in the presence of the membrana nictitans, in the anterior position of the nostrils, and in the situation of the mammæ, which are pectoral, or rather axillary, being situated just behind the roots of the flippers: in the female specimen examined, their base was about the size of a shilling, and they projected about half an inch from the surface. A considerable ridge extends along the middle of the upper surface of the posterior part of the back, which is continued upon and terminates in the tail."

The haunts of the Dugong, which does not appear ever to frequent the land or fresh-water, are generally in the sea-shallows, where the water is not more than two or three fathoms.

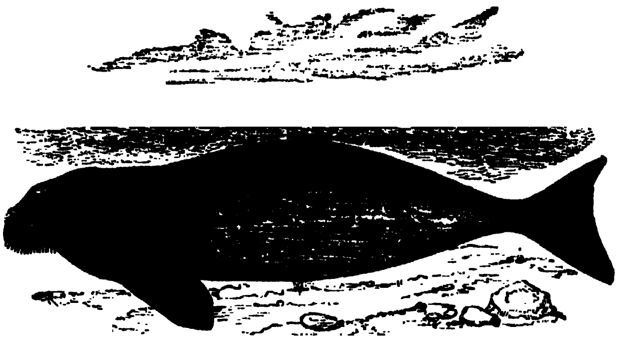
Sir Stamford Raffles states that during six months four of these animals were secured at Singapore, but that the greatest number is said to be taken during the northern monsoon, when the sea is most calm, near the mouth of the Johore River. They are usually caught by spearing, in which feat the natives are very expert, during the night, when the animals indicate their approach by a snuffing noise which they make at the surface of the water. The first object of the captor is to secure and elevate the tail, when the animal becomes perfectly powerless. Sir Stamford adds, that the Dugongs are seldom caught at Singapore above 8 or 9 feet in length; but how much larger they grow is not ascertained, as when they exceed that size, their superior strength enables them to make their escape.

Leguat, who speaks of them as occurring at the Isle of France in great numbers about 120 years ago, says that they were 20 feet long, but were very easily taken. They fed in flocks like sheep in three or four fathoms' water, and made no attempt at escape when approached. Sometimes they were shot at the end of the musket, sometimes laid hold of and forced on shore. Three or four hundred were met with together, and they were so far from shy that they suffered themselves to be handled, and the fattest were thus selected. The larger ones were avoided, not only on account of the trouble they gave in the capture, but because their flesh was not so good as that of the smaller and younger ones.

The female Dugong produces generally only one young at a birth, and to this the mother bears such strong affection that, if the young is speared, the mother will not depart, but is sure to be taken also. The Malays consider this animal as almost typical of maternal affection. The young utter a short and sharp cry, and are said to shed tears, which are carefully preserved by the common people as a charm, under the notion that they will secure the affections of those whom they love, as they attract the mother to the young Dugong.

The flesh of the Dugong is delicate, and is said to be superior to that of the Buffalo or common Ox. It is considered by the Malays as a royal fish, and the king has a right to all that are taken. Sir Stamford Raffles states that this species afforded much satisfaction on the table, as the flesh proved to be most excellent beef.

H. Tabernaculi, the Dugong of the Red Sea, is considered by Rüppell a distinct species. He gave it its specific name under the impression that it was with the skin of this species that the Jews were directed to veil the Tabernacle. He saw it swimming among the coral banks on the Abyssinian coast near the Dalac Islands. The fishermen harpooned a female, which he dissected, 10 feet long. The Arabs stated that they live in pairs or small families, that they have feeble voices, feed on *Algæ*, and that in February and March bloody battles occur between the males, which attain the length of 18 feet. The female brings forth in November and December. The flesh, teeth, and skin are esteemed by the Arabs.



Dugong (*Halicore Dugong*).

H. australis. It is a native of the north-west coast of Australia. It is the Manate of Dampier and the Whale-Tailed Manate of Pennant. Two upper jaws and three skulls of this species are in the British Museum.

Rytina gigas, the Morskaia Korova. It is the Manate, or *Vacca marina*, *Trichechus Manatus* of Müller; *Rytina Stelleri* of Illiger; *Stellerus borealis* of Desmarest; the Whale-Tailed Manate of Pennant. It is a native of the Arctic Ocean—Behring's Straits. The Sea-Ape of Pennant, *Trichechus Hydropithecus* of Shaw, *Manatus Simia* of Illiger, Dr. Gray suggests may belong to this family, if it is not a Seal.

Fossil Cetacea.

The fossil remains of *Cetacea* have hitherto been found in the Tertiary Formations only. Bones from the Portland Stone which were at first thought to belong to whales proved to belong to the genus *Cetiosaurus* (Owen), the most gigantic of all the fossil reptiles. (Owen, 'Report on British Fossil Reptiles' in 'Trans. Brit. Ass.' 1841.) Dr. Buckland, in his 'Bridgewater Treatise,' remarks that the seas of the Miocene and Pliocene periods were inhabited by marine *Mammalia*, consisting of Whales, Dolphins, Seals, Walrus, and the Lamantin or Manatee, whose existing species are chiefly found near the coasts and mouths of rivers in the torrid zone.

Manatidæ. Cuvier figures and describes the remains of a Manatee differing from the existing species. Specimens were collected from various parts of France, and he states it to be very certain that an animal of the genus *Manatus*, a genus now peculiar to the torrid zone, inhabited the ancient sea which has covered Europe with its shells, at an epoch posterior to the formation of the chalk, but anterior to that when the gypsum was deposited and the *Palæotherium* with its contemporary genera lived on the soil of France. ('Oss. Foss.')

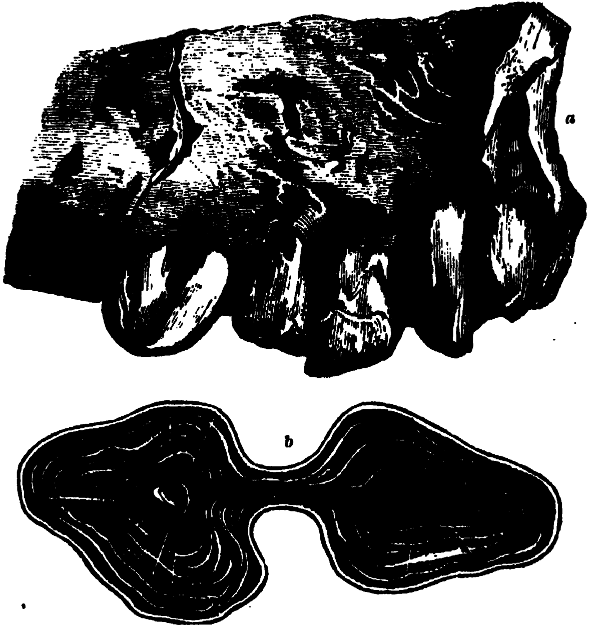
Delphinidæ. Cuvier notices and figures, with an accurate description, the remains of a fossil Dolphin, approaching the Grampus and *Delphinus globiceps*, from Lombardy, the skeleton of which was found nearly entire by M. Cortesi; and another with a very long symphysis of the lower jaw from the department of Landes. Also a fossil Dolphin closely approximating the common Dolphin from the same locality, and another from the Calcaire Grossier of the department of Orne. ('Oss. Foss.')

M. von Meyer refers to these and another (Grateloup, 'Ann. Géner. d. Sc. Phys.' iii., s. 58, t. 36; Taylor, 'Magazine of Nat. Hist.' March, 1830, s. 262), giving the following names:—*Delphinus Cortesii*, *D. macrogenius*, *D. longirostris*. ('Palæologica.')

Monodon. Cuvier collects notices of fossil fragments of the Narwhal from Parkinson and Georgi. He adds that he himself saw a broken piece of a tusk in the Cabinet of Natural History of Lyons which had formerly been in that of Pestalozzi. ('Oss. Foss.') Remains of the *M. monoceros* have been found in the neighbourhood of London and in other parts of England. (Owen, 'Brit. Foss. Mam.')

Ziphius. Cuvier founded this genus, which approximates the Cachalots and Hyperoodons, on crania discovered on the coast of Provence, and disinterred in excavating the docks at Antwerp, and on a fragment in the Paris Museum. On these materials he rests three species, namely—*Ziphius cavirostris*, *Z. planirostris*, and *Z. longirostris*, the remains of which he figures and describes. ('Oss. Foss.')

Zeuglodon. This name was given by Professor Owen to the *Basilosaurus* of Dr. Harlan. It was at first regarded as a reptile by its discoverer, but Professor Owen found that the microscopic characters of the texture of the teeth were strictly of a mammiferous character, and the nature of their investing substance limited the comparison of them with those of the few mammals in which the teeth are devoid of enamel. Among these are the *Edentata*, including the *Megatherium* and its congeners, the Morse, the Dugong, and the Cachalot. It is to the teeth of the Cachalot and Dugong that those of the so-called Basilosaur offer the nearest resemblance; and Professor Owen conceives that its position in the natural system was in the cetaceous order, intermediate between the Cachalot and the herbivorous species. In a paper read before the Geological Society of London, Professor Owen says, "The teeth, in their combination of an exaggerated condition of the conjugate form—which is but indicated in certain teeth of the Dugong, with two distinct fangs, in their oblique position in the jaw, and the irregular interspaces of their alveoli,—present very striking peculiarities; and when to these dental characters we add the remarkable and abrupt contraction of the distal end of the humerus, which is nevertheless provided with an articulating surface for a ginglymoid joint, and its remarkably diminutive size—a cetaceous character, which likewise is here carried to an extreme,—and when we also consider the dense laminated structure of the ribs, and the third exaggeration of a cetaceous structure in the extreme elongation of the body of the caudal vertebræ,—we cannot hesitate in pronouncing the colossal *Zeuglodon* to have been one of the most extraordinary of the *Mammalia* which the revolutions of the globe have blotted out of the number of existing beings."



Teeth of *Zeuglodon*.
a, Portion of upper jaw, containing three teeth, very much reduced; *b*, section of tooth.

In the 'American Journal of Science' for April, 1843, is a 'Notice of the Discovery of a nearly complete Skeleton of the *Zygodon* (*Zeuglodon*) of Owen (*Basilosaurus* of Harlan) in Alabama,' by S. B. Buckley, A.M.

The entire length of the skeleton, including the head, is described as nearly 70 feet, and was imbedded "in a marly limestone soil" on the plantation of Judge Creagh, the same gentleman who had forwarded the bones to Dr. Harlan. This discovery entirely corroborates the conclusions to which Professor Owen came in the memoir above quoted. Bones of this gigantic fossil Cetacean have been also found near the Washita River in Louisiana, and have been seen in Washington County, Mississippi: from thence, Mr. Buckley adds, they have been found in several places as far east as Claiborne, on the Alabama River. The skeleton is now at New York.

Balænidæ.—*Balænoptera*. Cuvier figures and describes the skeleton of a fossil whale, which he considers to have been a sub-genus of

Balænoptera, or Rorqual, found in Lombardy by M. Cortesi, on the east flank of Monte Pulgnasco (Apennines) in 1806. Cuvier calculates the entire length at 21 feet, French; observing, that if the animal was adult it was a very small Rorqual. Another skeleton of the same species, not more than 12 feet 5 inches long, was also discovered by M. Cortesi in similar beds, and a neighbouring valley near a small stream which falls into the Chiavenna, one of the tributaries of the Po. ('Oss. Foss.')

Balæna. Numerous remains of *Balænæ* have been found in the Tertiary Formations. Cuvier mentions a considerable fragment of the skull of a *Balæna* disinterred in the Rue Dauphine at Paris in 1779. Daubenton came to the conclusion that the whale to which it belonged must have been 100 feet long; but Cuvier, on satisfactory calculations, reduces the length to 60 feet, and states his opinion that it is an unknown species. ('Oss. Foss.') Dr. Mantell detected the remains of *Balæna* in Sussex (Brighton Cliffs). In the Red Crag of Felixstow the tympanic bones of whales are frequent, whilst their bones are so numerous as to constitute a considerable portion of the phosphatic substances which are now dug from this formation under the name of Coprolite. From the form of the tympanic bones, which he calls Cetotolites, Professor Owen has named four species of *Balæna*: *B. affinis*, *B. definita*, *B. gibbosa*, and *B. emarginata*. (Owen, 'Brit. Foss. Mam.')

Phocæna. Professor Owen refers the fossil found in the Lincolnshire fens to this genus, which Dr. Gray places under the genus *Orca*.

Physeteridæ. Teeth of the *Physeter macrocephalus* have been found in the Tertiary Beds of Essex and in other parts of Great Britain. From the section of a tooth found in the Red Crag at Felixstow, Suffolk, Professor Owen proposes to call the animal to which it belonged *Balænodon physaloides*.

(Cuvier, *Ossemens Fossiles*; F. Cuvier, *Histoire Naturelle des Cetacés*; Owen, *Descriptive and Illustrated Catalogue of the Physiological Series in the Museum of the College of Surgeons*; Scoresby, *An Account of the Arctic Regions*; Beale, *Natural History of the Sperm Whale*; Owen, *British Fossil Mammals and Birds*; Dr. J. E. Gray, *Catalogue of the Specimens of Mammalia in the British Museum*, Part I., '*Cetacea*;' *Cyclopædia of Anatomy and Physiology*, article '*Cetacea*.')

CETE. [CETACEA.]

CETIOSA'URUS, a genus of large Fossil Saurians adopted by Professor Owen. It occurs in the Oolitic Formations.

CE'TOCIS, De Montfort's generic name for those Belemnites which are plicated at the summits.

CETONI'ADÆ (M'Leay), a family of Coleopterous Insects of the section *Melitophili* (Latreille). The species belonging to this family have the sternum more or less prolonged into an obtuse point, between the second pair of legs; the mentum is emarginated, and never transverse; the terminal lobe of the maxillæ is furnished with a tuft of fine hairs; the labrum is concealed; the antennæ are small and ten-jointed; the basal joints are short; the three terminal joints are comparatively large, placed close together, and form a triphyllous knob. The thorax is generally somewhat triangular, with the anterior part (which would form the apex of the triangle) truncated. The elytra are usually rather straight at the sides, and obtusely rounded at the apex, thus presenting a somewhat square form; their disc is rather flat. A triangular scale is interposed between the base of the thorax and that of the elytra at their outer angles.

The *Cetoniadæ* form one of the most extensive groups of the Beetle Tribe, and nothing can exceed the brilliant colours with which many of them are adorned—in this respect vyeing with, if not surpassing, the *Buprestidæ*.

In the larva and imago states these insects feed upon vegetable substances: the grub or larva of the common Rose-Beetle very much resembles that of the cockchafer; and when about to assume the pupa state incloses itself in a cocoon formed of particles of earth and rotten wood, or any surrounding substances, fastened together by means of a glutinous secretion.

In viewing a large collection of insects of this family it is difficult to say what colours prevail most. In *Cetonia*, the typical genus of the group (in which the scutellum is of moderate size) the colours are generally burnished, and consist for the most part of various shades of green. *Cetonia aurata*, the common Rose-Beetle, affords a good example of this genus. It is about three-quarters of an inch in length, and of a bright green and sometimes copper-like colour, with two white irregular fasciæ towards the latter part of the ely[illegible] and extending from the side inwards: these fasciæ (and several little spots of the same colour which are observable on the elytra) are composed of a number of small scales, which in old specimens are often nearly all rubbed off. This species is too well known to require further description. It is seen very commonly in the south of England, flying about in the sunshine during the months of May and June, frequently settling on roses, the leaves of which it greedily devours; it is also very fond of elder and lilac flowers. If perchance the bark of a tree be wounded so that the sap oozes out, this insect will frequently be observed licking it up, and collecting it by means of the tufts of hair with which the maxillæ are terminated.

Rösel informs us, that he kept one of these insects alive for upwards of three years, during which time he fed it upon fruit and moist white bread.

Cetonia stictica, a small species, about half an inch in length, and of a black colour, with numerous white spots on the thorax and elytra, is said to have been taken in this country. Its occurrence is however so rare, that it is doubted by some if it be truly indigenous. It is common in France and Germany, and is found on thistles.

C. fastuosa, a species which somewhat resembles *Cetonia aurata*, but is of a larger size and without any spots, occurs in the south of France.

CETRARIA, a genus of plants belonging to the family of Lichens. The species have the following characters: — Thallus foliaceous, lobed, and laciniated; on each side smooth and naked; the shields are orbicular, obliquely adnate with the margin of the thallus, the lower portion being free; the disc coloured, plano-concave, with a border formed of the thallus, and inflexed.

C. Islandica, Iceland Moss. It is the *Lichen Islandicus* of older botanists. It has an erect, tufted, olive-brown thallus, paler on one side, laciniated, channeled, and dentato-ciliated; the fertile lacinia very broad. Shields brown, flat, with an elevated border. It grows on the ground in exposed situations in northern countries. The aqueous decoction when cold forms a thick jelly. It has a bitter flavour. It has been employed medicinally. [ICELAND MOSS, in ARTS AND SC. DIV.]

C. nivalis is an allied species growing on mountains in northern countries. It has similar properties to the last.

CEUTORHY'NCHUS, a genus of Coleopterous Insects, of the family *Curculionidæ* (Leach). The species have the antennæ eleven-jointed, seven of which compose the funiculus; the basal joint is as long as the remainder taken together; the club is ovate. Rostrum sometimes long, bent, and filiform, and at others short and straight. Thorax with the fore part much attenuated, with a channel beneath, in which the snout may be deposited. Scutellum minute and hardly apparent; the elytra are rounded at the extremity, and do not entirely cover the abdomen; the extremity of the tibiæ is without spine.

The little insects of which this genus is composed are very numerous, and frequent plants of various sorts; some scarcely exceed a mustard-seed in size. *C. didymus* is abundant on the common stinging nettle, and is about the size of a hemp-seed. It is white beneath, and of a dull brownish black above; the sides of the thorax are white, and the elytra are furnished with two spots of the same colour; the apex of the elytra is also more or less white. When touched, or often when even approached, these little beetles close their snout in a groove on the under part of the body, contract the legs, and allow themselves to roll off the leaves to the ground, where they are with difficulty distinguished from the mould.

CEVADILLA. [CEBADILLA.]

CEYX. [KINGFISHERS.]

CHABAZITE, a mineral belonging to the large class of *Aluminates*. It always occurs in the form of attached crystals; never massive or fibrous. The primary form of the crystal is a rhomboid. The colour is white, also yellowish and red. The lustre is vitreous, and it is transparent to translucent. The hardness is 4 to 4·5. The specific gravity is 2·06 to 2·17. It has the following composition:—

Silica	48·4
Alumina	19·3
Lime	8·7
Potash	2·5
Water	21·1
	100·0

This species includes *Gmelinite*, which occurs in small glassy crystals; also *Levyne*, which is found in compound crystals; and *Ledererite*, which has the form of Gmelinite, but differs in containing just one-third the quantity of water. *Phacolite* is another variety. It occurs in the form of small glassy crystals, which are double six-sided pyramids. *Acadiolite* appears to be another variety. It has a red colour, and comes from Nova Scotia. *Herschelite* is another variety. It occurs in small hexagonal tables.

Chabazite is mostly easily distinguished by the nearly cubical form presented by its crystals. From *Analcime* it is distinguished by the intumescence produced by it under the blow-pipe. It is distinguished from *Calc-Spar* by its hardness and its action with acids; from *Fluor-Spar* by its form and cleavage, and by the absence of phosphorescence.

It is found in Trap, Gneiss, and Syenite. In the New World it is found in the Trap of Connecticut, in New Jersey, and New York. *Ledererite* is found in Nova Scotia. *Chabazite* is found in the Faroe Islands, at the Giant's Causeway, Ireland, also in Iceland. *Gmelinite* is found in Antrim, Ireland. *Levyne*, at Glenarm in Ireland; also in Scotland, Iceland, and the Faroe Islands.

CHACMA. [BABOON.]

CHÆRADODIA, a genus of plants belonging to the natural order *Amaryllidaceæ*. One species of this genus, *C. Chilensis*, is called Thekel in Chili. A cold infusion of the leaves is used as a purgative and diuretic medicine by the natives.

CHÆROPHYLLUM, a genus of plants belonging to the natural order *Umbelliferæ*, to the sub-order *Campylospermæ*, and the tribe *Scandicineæ*. It has an obsolete calyx; obcordate petals with an inflexed point; a fruit not beaked; carpels with five equal obtuse ridges; interstices with single vittæ. The species are annual, biennial, or perennial plants with decompound leaves. Many plants formerly placed in this genus are now referred to *Anthriscus*. [ANTHRISCUS.] The *Chærophyllum sylvestre* of Linnæus is now *Anthriscus sylvestris*. It has been used in medicine as a substitute for hemlock. The *Chærophyllum sativum* of Lamarck is the *Anthriscus cerefolium* of Hoffman. It is the garden Chervil of Great Britain, and is used in some places as a pot-herb. Three species of *Chærophyllum* are described by Babington in his 'Manual of British Botany:' *C. temulum* has a rough stem swelling beneath the joints; the leaves bipinnate; the leaflets ovate, oblong, pinnatifid, with obtuse mucronate segments; glabrous petals; styles equalling the stylopode. It is a common plant on hedge-banks in Great Britain, attaining a height of three or four feet. *C. aureum* and *C. aromaticum* have been described as natives of Scotland, but it is very doubtful as to whether they have not both been introduced. (Babington, *Manual of British Botany;* Lindley, *Flora Medica.*)

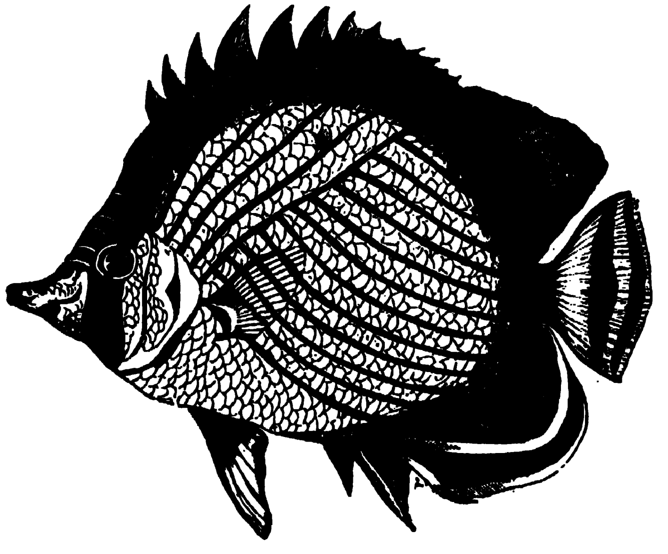
CHÆ'TODON (χαίτη, hair, and ὀδοὺς, a tooth), a genus of Fishes of the section *Acanthopterygii* and family *Squammipennes*. It has the following characters:—Body compressed; mouth small, furnished with several closely-set rows of long slender bristle-like teeth. The scales (which are usually confined to the body) in this genus extend on to the dorsal and anal fins, so that it is difficult to see where the latter commence.

These fishes abound in the seas of hot climates, frequent rocky shores, and are adorned with beautiful colours. Their most common tints appear to be black and yellow, but brilliant metallic blues and greens of various hues are not unfrequent. Many of the species have a vertical black band in which the eye is placed. In some there are several similar vertical bands on the body; in others the body is spotted or adorned with oblique or longitudinal bands. They have a large air-bladder; their intestines are long and ample; and their cœca are numerous, long, and slender. Their flesh is good eating.

The species are numerous, and have been divided into several sub-genera; those to which the name *Chætodon* is now restricted have the body more or less elliptical, the rays of the dorsal fin forming a tolerably uniform curve, the snout more or less produced, and the pre-operculum sometimes furnished with a small tooth.

In some of this section one or more of the soft rays of the dorsal fin are much produced, and form a long filament; and others are distinguished by their having very few spines to the same fin.

Chætodon vagabundus, a species which inhabits the coasts of Ceylon, has the body of a pale yellow colour, with numerous oblique brownish-purple lines; the dorsal fin is blackish, and has 13 spinous rays; the caudal fin, or tail, is yellow, with two black bands; the anal fin is blackish with a yellow curved longitudinal band; its margin is also yellow; a broad black vertical band extends through the eye; and the part anterior to this band, as low down as the eye, is of a pinkish hue with yellow streaks. Its length is from 6 to 12 inches; the scales on the body are large; those on the head are rather small.



Chætodon vagabundus.

The next sub-genus, *Chelmon* (Les Chelmons, Cuv.), is distinguished by the form of the snout, which is much elongated, open at the end only, and formed by a great elongation of the intermaxillary and under-jaw bones.

C. rostratus, a species which inhabits the fresh waters of India, is of a silvery hue and has five brownish bands; the posterior part of the dorsal fin is furnished with a black spot encircled with white.

This fish feeds upon insects, and is remarkable for its mode of procuring them. When it observes a fly or any other insect on a weed, or hovering over the water, it ejects a little drop through its tubular snout with such precision as frequently to disable the little animal, so that it falls into the water and is devoured.

In those parts where *C. rostratus* abounds it is frequently kept in vessels of water, and affords much entertainment by the dexterity displayed in shooting at flies which are placed on the vessel for the purpose: it generally approaches to within five or six inches before the drop of water is ejected.

The sub-genus *Heniochus* differs from the true Chætodons in having the anterior spines of the back produced into a long filament, which is sometimes double the length of the body.

Ephippus may be distinguished by the species having the dorsal fin deeply cleft between the spinous and soft portions. The spiny portion, which is scaleless when not erected, is received into a groove formed by the scales of the back.

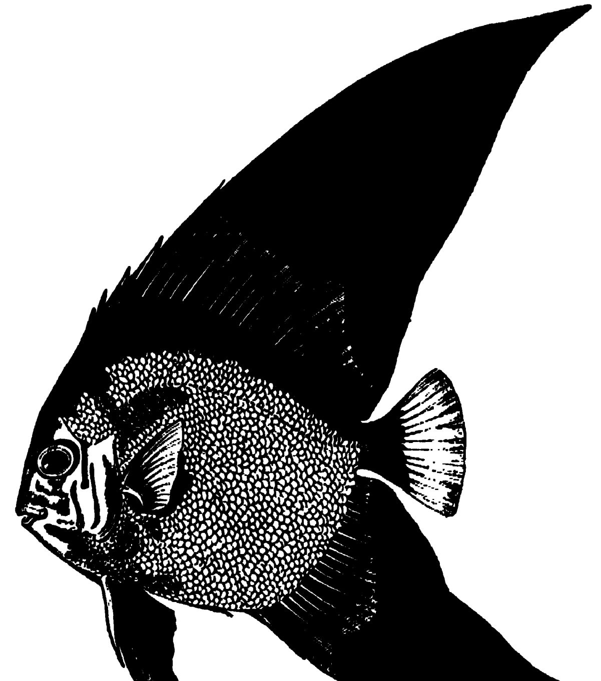
Holocanthus. The species of this sub-genus have a large spine on the angle of the pre-operculum, and most of them have the edge of the same bone serrated: they are found both in the Atlantic and Pacific oceans.

The next subdivision, *Pomacanthus*, has the body of a more elevated form, owing to the sudden rising of the anterior margin of the dorsal fin. The only species known are from the American coasts.

In the last subdivision, *Platax*, the species may be known by the extremely compressed form of the body, the large vertical dorsal fin (which has the anterior spines almost concealed in the membrane), the long ventral fins, and the teeth. Here, in addition to the fine thickly-set teeth, there are some in front which are trenchant, and each of them is divided into three points.

All the species of this section are found in the Indian Ocean. One has been found in a fossil state at Mount Bolca.

Platax vespertilio will afford an example of this section. It is found off the coast of Ceylon, and is of a yellowish colour; the dorsal, anal, and ventral fins are brownish, the back is also mottled with the same colour, and a dark band extends downwards through the eye; the base of the caudal fin is dark brown. This species grows to a large size, and is found in rocky situations, but more commonly in deep water.



Platax vespertilio.

The two species of Chætodons, of which figures are here given, have been selected from Mr. J. W. Bennett's 'Fishes of Ceylon,' a work illustrated by beautiful coloured plates.

(Cuvier, *Règne Animal;* Lacépède, *Histoire Naturelle, &c., des Poissons;* Bloch, *Histoire Naturelle, générale et particulière, des Poissons.*)

CHAFFINCH, the English name for a well-known species of *Fringilla*: Σπίζα of Aristotle and the Greeks; *Fringilla* and *Frigilla* of Gesner and others; Franguello, Frangueglio, Fringuello, and Spincione, of the Italians; Pinson, Pinçon, Grinson, and Quinson, of the French; Fink, or Buch-Fink (Beech-Finch), Edel-Fink, Gemeine-Fink, Schild-Vink, of the Germans, &c.; Fincke and Bofincke of the 'Fauna Suecica;' Asgell-Arian, Winc, of the ancient British; *Fringilla cœlebs* of Linnæus. It has also the following local names in English:—

Spink, Beech-Finch, Pink, Twink, Skelly, Shell-Apple, Horse-Finch, Scobby, Shilfa, Chaffy, Boldie.

As far back as the time of Belon the powerful voice of this bird was remarked:—"On les garde en cage pour les faire chanter, dont le chant est si puissant qu'il en est fascheux" (folio, 1555); and in the small quarto (1557) the following quatrain is printed under the figure of the bird:—

> Pour bien pinser lon me nom Pinson,
> Qui ay la voix fort haultaine et puissante;
> Je hay le chauld, froidure m'est plaisante;
> En ce contraire est à tous ma façon.

"The passion for this bird," says Bechstein, in his 'Cage Birds,' "is carried to such an extent in Thuringia, and those which sing well are sought for with so much activity, that scarcely a single chaffinch that warbles tolerably can be found throughout the province. As soon as one arrives from a neighbouring country whose notes appear good, all the bird-catchers are after it, and do not give up the pursuit till they have taken it. This is the reason why the chaffinches in this province are so indifferent songsters; the young ones have only bad masters in the old ones, and they in their turn cannot prove better."

In England however it appears to have been appreciated. The Hon. Daines Barrington, in his paper 'On the Small Birds of Flight' (the bird-catcher's expression), observes that the greatest sum he ever heard given for a song-bird which had not learned to whistle tunes, was five guineas for a Chaffinch that had a particular and uncommon note, under which it was intended to train others. Bechstein says the Thuringians have been known to give a cow for a Chaffinch with a fine voice.

Bechstein, after describing the different notes that express its passions and wants, among which the often-repeated cry, 'fink, fink' (our 'twink'), from which its German name is derived, he considers to be mechanical and involuntary, thus speaks of its powers:—"But what makes it appear to still more advantage among other birds are its clear and trilling tones that seem almost to approach to words; in fact, its warbling is less a song than a kind of battement, to make use of a French word, and is expressed in German by the word schlag (trill), which is used to designate its song as well as the nightingale's. Some chaffinches have two, three, four, even five different battemens, each consisting of several strains, and lasting several minutes. This bird is so great a favourite in Germany that not a single tone of its voice has escaped the experienced ears of our bird-fanciers. They have observed its nicest shades, and are continually endeavouring to improve and perfect it. I confess I am myself one of its warmest admirers; I have constantly around me the best songsters of its species, and if I liked could write a good sized volume on all the details of its music."

The following chaffinch songs, or melodies, are most esteemed in Saxony and Hesse. Some are heard in the woods, but they are rarely sung with a clear and strong voice. If the bird executes well, and adds to the last strain the sound 'fink,' which the German bird-catchers translate by 'amen,' it is of the highest value. "No price," says Bechstein, "will be taken for it."—

1. The 'Double Trill of the Harz,' in Lower Saxony. 2. The 'Reiter Zong,' or 'Rider's Pull,' first heard among the mineral mountains of Saxony and Voigtland. 3. The 'Wine Song,' with the following subdivisions, namely:—The 'Fine,' or 'Längsfeld Wine Song;' the 'Bad Wine Song' and the 'Sharp Wine Song,' which is subdivided into the 'Common Sharp' and the 'Ruhl Sharp.' 4. The 'Bräutigam,' or 'Bridegroom Song,' also divided into good and bad. 5. The 'Double Trill.' One of these, the 'Double Trill of Iamblach,' is only to be acquired in the house, and is so deep and powerful that it can scarcely be conceived how the larynx of so small a bird can produce such sounds. Bechstein, who makes this observation, adds that a Chaffinch which sings this either alone or with the 'Good Bridegroom's Song' (such as are educated at Iamblach), sells at Waltershausen for eighteen French francs. 6. The 'Gutjar,' or 'Good Year Song,' with two subdivisions. Chaffinches singing this, united to the 'Wine Song' of Ruhl, or the 'Sharp Song,' had become very rare when Bechstein wrote, and fetched high prices. 7. The 'Quakia Song,' formerly much admired. Bechstein says, "I believe [illegible] possess the only bird that is now to be found which sings this. [illegible] be admired the 'Quakia' must be united with the 'Double Tr[illegible] This my chaffinch sings also." 8. The 'Pithia,' or 'Trewethia,' [illegible] very uncommon and agreeable song, never heard but in the depths of the Thuringian mountains.

For the different modes of capturing this pretty bird, so precious when in pefect song to the bird-fancier, its treatment in confinement, the diseases to which it is subject, and their remedies, we must refer the reader to Bechstein's 'Cage and Chamber Birds,' of which there is an English edition published by Bohn (1853).

The following description—and the bird is so common that a more particular one is unnecessary—is from the interesting 'Journal of a Naturalist':—"The male bird is remarkable for the cleanliness and trimness of his plumage, which, without having any great variety or splendour of colouring, is so composed and arranged, and the white on his wings so brilliant, as to render him a very beautiful little creature. The female is as remarkable for the quiet unobtrusive tintings of her dress; and when she lies crouching on her nest, elegantly formed of lichens from the bark of the apple-tree, and faded mosses, she would hardly be perceptible but for her little bright eyes that peep with suspicious vigilance from her covert." Temminck says, that in autumn after the moult, the colours of the plumage of the male are more bright than they are in the spring, because all the feathers of the upper and lower parts are terminated by a clear ash-colour; and, at the season of love, the male bird's dress becomes decked with pure and brilliant colour, without the aid of a second moult, the edges of the barbs being worn away with use, and thus suffering those colours which had been hidden to appear in all their beauty.

Many varieties occur, as pure white, yellowish white, some parts of the body white. The usual colours with a white collar; wings and tail white. Aldrovandus mentions one partly yellowish and partly blackish.

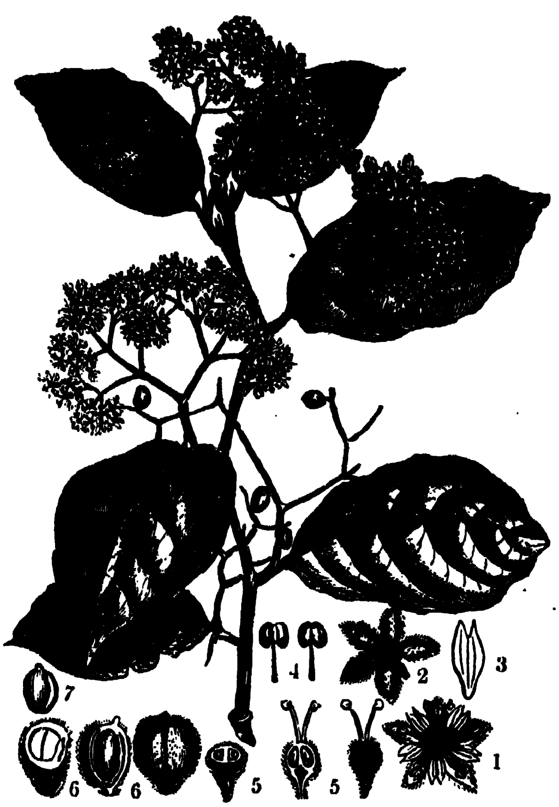
This bird inhabits almost all the countries of Europe; it is permanent in the southern parts, and a regular bird of passage in the greatest number of localities. The Prince of Canino says that it is very common near Rome, and makes its passage in October, when numbers of them are taken for the table among other small birds at Paretajo and Roccolo, but in much the larger proportion, 500 chaffinches being, according to the Prince, captured to every 80 linnets, 65 goldfinches, 30 green grosbeaks or greenfinches, &c., &c. It has been stated and denied, that only the females of this bird are migratory in Europe. On this point Selby observes, "In Northumberland and Scotland this separation takes place about the month of November, and from that period till the return of spring, few females are to be seen, and those few always in distinct societies. The males remain, and are met with, during the winter, in immense flocks, feeding with other granivorous birds in the stubble lands as long as the weather continues mild and the ground free from snow; and resorting, upon the approach of storm, to farm-yards and other places of refuge and supply. This separation of the sexes I am induced to believe takes place in many other species, with respect to their migratory movements, as I have before remarked in the account of the snow-bunting. This appears also to be the case with the woodcock, having observed that the first flight of these birds (which seldom remain longer than a few days to recruit, and then pass southward) consists chiefly of females; whilst, on the contrary, the subsequent and latest flight (which continue with us) are principally composed of males. It has been noticed by several authors that the arrival of the males, in a number of our summer visitants, precedes that of the females by many days; a fact from which we might infer that in such species a similar separation exists between the sexes during their equatorial migration." Knapp ('Journal of a Naturalist') says, "With us (Gloucestershire) the sexes do not separate at any period of the year, the flocks frequenting our barn-doors and homesteads in winter being composed of both. In the northern parts of Europe however the females are said to migrate to milder regions, which induced Linnæus to bestow the name of *Cœlebs* upon this species." White observes upon the vast flocks which he saw near Selborne towards Christmas, all of which were hens. Jenyns says that it collects in flocks at the approach of winter, but makes no mention of the separation of the sexes. In Middlesex we have seen in winter flocks composed mostly of females, but we have also seen both sexes, about Christmas, partaking with other little winged pensioners of the crumbs daily thrown out for their support.

The Chaffinch feeds principally on seeds. We are however compelled to add that they are very injurious to the florist and gardener. "These birds," says Knapp, "make sad havoc with some of our spring flowers; and the polyanthus, in March, in our sheltered borders, is very commonly stripped of all its blossoms by these little plunderers, I suppose to obtain the immature seeds at the base of their tubes. . . . . At this period too they are sad plunderers in our kitchen gardens, and most dexterously draw up our young turnips and radishes as soon as they appear upon the surface of the soil; but after this all depredation ceases, the rest of their days being spent in sportive innocence." Selby says that in summer it feeds much upon insects and larvæ, and that he has witnessed its assiduity, during the autumn, in devouring the females of a large species of aphis, that infests the trunks and stronger branches of the larch and some other kinds of fir. In winter, he adds, grain and other seeds constitute its food.

Like the other finches it builds one of the most beautiful nests, and, as Selby observes, always accordant with the particular colour of its situation. It is variously placed in trees and bushes. In orchards an old apple-tree is a favourite situation. Eggs, four or five, bluish-white, tinged with pink and marked with streaks and spots of purplish-red.

CHAILLETIA'CEÆ, *Chailletiads*, an obscure natural order of Polypetalous Exogens, some of whose species are said to be poisonous. They are very near *Rhamnaceæ*, from which they differ in having the stamens alternate with the petals, and five hypogynous glands. The petals are small scale-like bodies stationed at the orifice of a tubular calyx; the ovary is superior, and two or three celled, the ovules pendulous, the fruit somewhat drupaceous, and the seeds without albumen.

Chailletia toxicaria is called Ratsbane in Sierra Leone. The order embraces four genera and ten species.



Chailletia pedunculata.

1, an expanded flower; 2, the back of ditto; 3, a petal; 4, stamens; 5, different views of the ovary; 6, different views of the fruit; 7, an embryo.

CHALA'ZA, that part in a seed where the vessels of the raphe pass from the exterior integument or primine, and expand into the secundine. In the common almond it is readily seen by turning the testa inside out and observing that part which corresponds to the apex of the cotyledons. When the foramen of a seed is next the hilum, the chalaza is most conspicuous; but when the foramen is at the apex of a seed, the chalaza will then be in contact with the hilum, with which it must necessarily be then confused.

CHALCEDONY. [AGATE.]

CHA'LCIDES, Daudin's name for a family of Lizards, which, like the Seps-Lizards, are very long and serpent-like; but whose scales, instead of being imbricated or disposed like tiles, are rectangular, and form, like those of the tail in the ordinary lizards, transverse bands which do not intrench upon each other. Some, says Cuvier, have a ridge on each side of the trunk, and the tympanum still very apparent. They approach the *Cordyli*, as the Seps-Lizards approach the *Scinks*, and lead by several relations to the *Sheltopusicks* and *Ophisauri*. The *Chalcides* have four legs, but they are little developed, and the extremities may be considered as in a degree rudimentary; for some of them cannot be said to be furnished with more than one well-formed toe on each foot, though there are traces or rudiments of more. Cuvier thus arranges the family:—

A species with five toes from the East Indies, *Lacerta Seps* of Linnæus.

A species with four toes, *Lacerta tetradactyla* of Lacépède; *Chalcis tetradactyla*. The genus *Tetradactylus* of Merrem; *Saurophis* of Fitzinger.

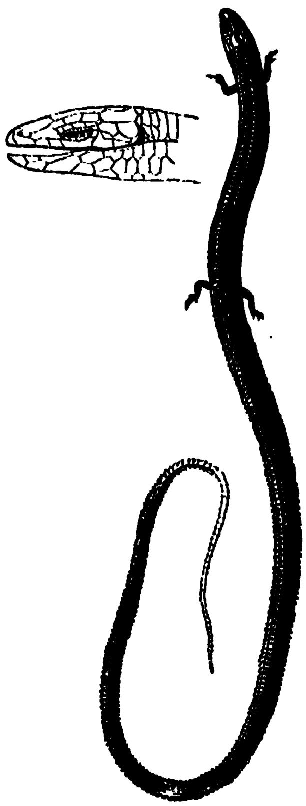
A section which have the tympanum concealed, and leading directly to the *Bimana* (*Chirotes*), and thence to the *Amphisbænæ*. Of these, there is a species with five toes, forming the genus *Chalcides* of Fitzinger.

A species from Brazil, with four toes before, and five behind, *Heterodactylus imbricatus* of Spix.

A species with four toes on each foot, forming the genus *Brachypus* of Fitzinger.

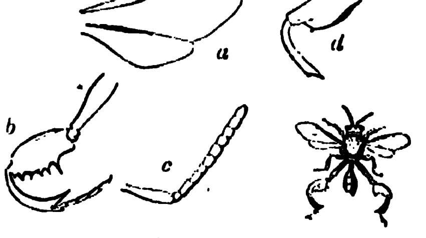
A species from Guyana, with five toes before, and three behind, but reduced to small tubercles so little visible that the species has been regarded at one time as having three toes, and at another as having but one. Cuvier adds, that on the first supposition, it is the *Chalcide* of Lacépède, pl. xxxii.; the *Chamæsaura Cophias* of Schneider; the genus *Chalcis* of Merrem; and the genus *Cophias* of Fitzinger; and that upon the second hypothesis, it is the *Chalcide monodactyle* of Daudin; the genus *Colobus* of Merrem; but, adds Cuvier, all these genera resolve themselves into a single species.

Chalcis tetradactyla has been given as an example of the family. It is the *Saurophis Seps* of Fitzinger, and under the name of *S. tetradactylis* is referred by Gray to his family *Cordylcs*. [SAURIA.]



Chalcis tetradactyla.

CHALCI'DIDÆ, a family of Hymenopterous Insects, of the section *Pupivora* (Latreille). Nearly all the species are exceedingly minute. Many are very brilliant, their colours consisting of various shades of green, blue, or copperlike hues; in some of the sections however black is the prevailing colour. The thorax is usually large in proportion to the body, and the latter is often of a compressed form, and joined to the thorax by a distinct long petiole or stalk, as in *Chalcis clavipes*, which is one of the largest of the British species, measuring from tip to tip of the wings when expanded upwards of half an inch; it is of a dull black colour, and remarkable for the excessive development of the coxiæ and femora of the hinder legs; the latter are of a reddish hue, and armed with eight little teeth beneath; the hinder tibiæ are curved. It is found on the leaves of shrubs in marshy situations.



Chalcis clavipes.

a, The wings; *b*, the hind-leg; *c*, antenna, magnified; *d*, hind femur and tibia of a species of *Donacia.*

In the species just described the oviduct is short, and hidden beneath the abdomen, a circumstance very common in this tribe; in some however the oviduct is very long, equalling or exceeding the body in length. This is the case in the genus *Callimome*, a group the species of which have very brilliant colours, principally green, and deposit their eggs in the larvæ of the Gall Insects (*Cynipidæ*), an operation which their long bristle-like ovipositors enable them readily to perform. Here, as in the genus *Chalcis*, the body is compressed. Many of the species however have that part depressed. One of the most striking characters in the *Chalcididæ* is in the wings, which are almost destitute of nervures. Most commonly there is in the superior wing a single nervure springing from the base and running parallel with the exterior margin for about one-third of the whole length of the wing. It then slopes upwards and joins the margin itself; and a little beyond the part where the slope takes place there is a small short ramification thrown out obliquely, which is generally thickened towards the extremity, and forms a little dark spot. The antennæ are always elbowed, that is, the terminal joints are bent forward at an angle with the basal joint. We have observed that when these little insects are about to leap, which a great portion of them have the power of doing, they invariably bend their antennæ under the body, and it appeared that this organ was used in making the spring. If this should be the case, it would be a most extraordinary use to make of those parts, which are usually considered either as organs of hearing or touch. We may observe that the species which we found to possess this power in a high degree had immensely thick antennæ, and the hind legs, the usual leaping organs, do not appear at all adapted for that purpose, nor can we discover any other part that is. Although in *C. clavipes* (the species figured) the hinder femora are thick, yet it does not possess the power of leaping; and when we examine the structure of this part, we find that it differs much from the thickened thigh of leaping insects. It is formed upon the same type as the same part in some of the *Donacia* tribe (among beetles), which appears to be used for clinging, and this species, inhabiting marshy situations, would probably require such a clinging apparatus for the same reason as the *Donaciæ* do, namely, to keep them from falling into the water. A figure of the leg of a species of *Donaciæ* is given, to show the resemblance both in the femur and curved tibia.

The *Chalcididæ* are all parasitical in their larva state. Some are so minute as to undergo their metamorphosis in the eggs of other insects. The chrysalides of some of the lepidopterous insects not unfrequently form the nidus of an immense number of these little insects. One species of *Chalcis* generally confines its attacks to the chrysalis of one species of lepidopterous insects; but occasionally we have reared more than one species of the *Chalcididæ* from the same chrysalis.

Mr. Walker, a gentleman who has written much on this group of insects, looks upon it as a great section of *Hymenoptera* rather than a family, and his views appear to us correct. The *Chalcididæ* are divided by him into two sections, which he calls *Chalcides Pentameri* and *Chalcides Tetrameri*, names applied from their having five or four-jointed tarsi; each of these sections is again subdivided into several families, the species of which are exceedingly numerous. Mr. Westwood, who, as well as Mr. Walker, has paid great attention to this interesting group, states that there are probably 1500 species in England.

CHALCOLITE, a mineral of a green colour containing Uranium. [Uranium.]

CHALI'COMYS, a genus of Rodent *Mammalia*, allied to the beaver. From Eppelsheim; in Tertiary beds.

CHALICOTHE'RIUM, a genus of Fossil Pachydermatous Animals allied to the Tapirs, comprising two species found at Epplesheim, about 12 leagues south of Mayence, in sand, supposed to be of the Second Tertiary or Miocene period of Lyell. (Kaup, *Description d'Ossemens Fossiles*, Darmst., 1832.)

CHALILITE, a mineral belonging to the group of Zeolites. It occurs massive. Its fracture is splintery and flat conchoidal. Hardness 4·5. Colour deep reddish-brown. Lustre between vitreous and resinous. Translucent on the edges. Specific gravity 2·252.

By the blowpipe it becomes white, and spreads out; with carbonate of soda it effervesces, and fuses with some difficulty into a white bead with a pearly lustre; with borax it fuses into a colourless glass. It is found in the county of Antrim, Ireland.

CHALIMUS, a genus of Entomostracous *Crustacea* allied to *Caligus*. [Caligus.]

CHALK FORMATION and **CRETACEOUS GROUP**, in Geology, consist of the upper strata of the Secondary series immediately below the Tertiary series and superincumbent on the Wealden, or where that is wanting, on the Oolitic system. This group is common to Europe, and also to at least a part of Asia. It consists of chalk resting upon either an arenaceous or argillaceous deposit. The Chalk bears a remarkably uniform mineralogical character over a surface extending from the British Islands through Northern France, Northern Germany, Denmark, and Sweden, into both European and Asiatic Russia. (De La Beche, 'Res. in Theor. Geol.') The Cretaceous system is subdivided into the following strata :—

Chalk	Upper.	1. Mæstricht beds	In which numerous species of marine fossils are found.
	Lower.	2. Chalk with flints	
	Marly.	3. Chalk without flints, and Chalk with marl	
Greensand	Upper Greensand		
	Gault		
	Lower Greensand (*Neocomien*)		

The area over which this system prevails in England, and the various strata which it contains, have been well defined by geologists.

The Cretaceous Group occupies nearly the whole of the south-eastern part of England. A line drawn from Crewkerne on the south-west to Hunstanton on the north-east forms its western boundary; and it extends from this line to the east coast, with the exception of a small part on the south-east. It is also found on the north of the Wash forming the Wolds of Lincolnshire. It is intersected by the Humber and constitutes also the Wolds of Yorkshire. It terminates near Flamborough Head at Speeton, about six miles north of that promontory. The same formation appears to prevail in the north of France, extending to the Cretaceous district of Aix-la-Chapelle. The Chalk, or upper portion of the system, is in some parts covered with the strata of the Tertiary series; in other parts it is denuded. The Greensand crops out round its edge, which is broken and interrupted in many places where the lower strata appear.

On the north-east the Chalk appears in a narrower belt along the cliff from near Cromer to Hunstanton. From Cromer along the coast to the mouth of the Thames, and along the north bank of that river, it is concealed by the upper strata, which extend a considerable distance inland.

Beginning with Norfolk and proceeding southwards, the boundary line between the Chalk and the superior strata is about 4 miles east of Snettisham, 2 miles west of Diss, 8 miles east of Mildenhall, between 4 and 5 miles west of Bury St. Edmunds, continuing to the north-east of Hertfordshire by Hertford and near St. Alban's, to 3 miles south-east of Wendover.

In the northern part of this district the Chalk has in a few places been partially denuded. On the north-east there is a small piece of Chalk along the banks of the Bure. The town of Norwich also stands upon Chalk, which, in its vicinity, extends along the banks of the Yare and Wensum. There is a piece of Chalk likewise at each side of small parts of the Stour and of the Orwell. The strata superincumbent on the Chalk series extend a little beyond Uxbridge on the west, and then run in a narrow tongue to the north-west, 3 miles south of Wendover, which intervening space at that point is the whole width of the denuded Chalk, Wendover being there its western limit. The Chalk becomes wider towards the south-east, taking in Maidenhead; it is again partially covered a little to the west of that place, and continues in a very uneven line to Reading, Newbury, and a little to the east of Marlborough. The Tertiary strata then run from west to east by Kingsclere, Basingstoke, Guildford, to 3 miles north of Dorking, round by the Darent, and appear near Woolwich and Greenwich. Another detached portion appears in the north-west of Kent, taking in the Isle of Sheppey, and continues from the æstuary of the Medway along the coast to the Isle of Thanet. The Chalk is covered on the west and north of Canterbury and at Sandwich; the beds which cover it terminate on the coast at Deal. On the south coast, from Worthing westward, the Chalk is again concealed by the superincumbent series, extending nearly in a straight line through Chichester as far as a little to the east of Salisbury; it then continues in a south-west direction nearly as far as Dorchester. The Chalk passes entirely across the Isle of Wight nearly from east to west, in a narrow ridge consisting of vertical strata, from Culver Cliff to Compton Bay; there is also a small piece on the south of the island. The limits of the Chalk on the other side, where it is bounded by the outcropping of the lower strata of the system, remain to be noticed. The cliffs of the whole of the Isle of Thanet are composed of Chalk. The chalk-cliffs again commence near Deal, and are continued past Dover to East Weare Bay, a distance of about 13 miles. As the Chalk rises from Dover towards Folkstone the upper beds disappear, and the cliffs consist entirely of the lower members of that stratum. The rise of the Marly Chalk occurs about 1½ mile to the east of the escarpment of Folkstone Hill, which is 566 feet high. Just at the rise of this bed there is a very copious and perennial spring called Lydden Spout. About 2000 paces west of this spring the cliff recedes from the sea, and the intermediate shore thence to Copt Point is occupied by a mass of ruins which has fallen from above. The sudden transition from the chalk-cliffs is very remarkable. Turning inland the chalk-range is bounded on the south by the outcrop of the Greensand strata, which extend 4 miles north of Ashford, 3 miles north of Maidstone, and is cut by the Medway, whence it forms a line curving outward to the south as far as the Darent, where it is 5 miles north of Sevenoaks. Merstham is on the boundary, which then continues in nearly a west direction, immediately north of Reigate to Box Hill, near Dorking, and thence to Guildford, leaving a very narrow ridge of Chalk. From Guildford to a point about 2 miles from Farnham there is a remarkable ridge, called the Hog's Back, produced by an upthrow of the Chalk and the breaking off of the southern portion of the curve. The coast between Copt Point and Beachy Head, near these respective points, is occupied on each side by the Greensand, and the intermediate space by the Wealden Clay and Hastings Sand: the two latter do not belong to this series, being lower denuded strata. The Sussex chalk-range, or South Downs, commences at Eastbourne, near Beachy Head, and continues thence along the coast beyond Shoreham and onwards in a west-by-north direction. The Greensand bounds it on the north, and leaves a range of Chalk varying from 8 to 3 miles in breadth. About 3 miles south-west of Petersfield the Greensand again sinks below the Chalk, which is connected with the north range by the Alton chalk-hills, running from near Farnham to near Butser Hill (917 feet).

It now remains to define the boundary of the Chalk from Dorsetshire on the south-west to Norfolk on the north-east. It has been thus described by Dr. Fitton :—"The great range of the chalk-escarpment in the interior of England, which stretches like the shore of a sea or lake from Crewkerne in Dorsetshire to the north-east of Dunstable in

Bedfordshire, is perfectly analogous in structure and appearance to the Downs of Surrey and Sussex. It is interrupted by three or four indentations or gulfs; one of great width, opening towards the west between Crewkerne and the heights about Stourhead, in South Wiltshire; another expanding to the north-west, and terminating in the defile where the Thames cuts through the chalk in its way to the south-east from Buckinghamshire and Oxfordshire. The vales of Pewsey and of Warminster are intermediate bays of the same general structure, but of smaller dimensions; and all these valleys are apparently the result of denudation, aided by previous disturbance of the strata, which has carried away the chalk, and laid bare to various depths the strata beneath it." ('Geol. Tran.,' 2nd series, vol. iv. part 2nd., p. 243.) From the heights near Dunstable the Upper Chalk range passes through the north-west of Hertfordshire, by Hitchin and Baldock, to Barkway and Royston Downs, and thence by Balsham and Newmarket into Suffolk by Mildenhall, 2 miles west of Brandon, 4 miles west of Downham, by Narborough, and on to Snettisham. The chalk-hills decline rapidly in height in the north-east of Bedfordshire. Kensworth Hill is 904 feet above the level of the sea; the hills east of that town are 850 feet high. Lilleyhoe is 664 feet; Barkway Windmill, 513 feet; the station near Royston, 484 feet; Balsham, on the east of Cambridge, 380 feet; Newmarket station, 267 feet; Brandon, in Suffolk, 190 feet. The chalk-hills stretching from Cambridgeshire to the north-west coast of Norfolk rise nowhere probably above 600 feet in height, bounding "the fen country like the low shore of a sea."

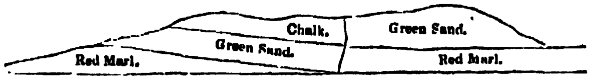
The Chalk Inland Range is highest towards the central part between Wiltshire and Hertfordshire. In departing from that central tract the rise is comparatively small both towards Devonshire on the south, as well as in the counties northwards. The Chalk nearly disappears in Devonshire, a few insulated portions only appearing there, principally upon the coast between Sidmouth and Lyme, and along a line from Beaminster through Chard and White Stanton. The transition from the Chalk to the Greensand is here distinctly seen, especially on the south-west of Axmouth, where sections of the subjacent beds are exposed in the cliffs. In many parts of the chalk-range the upper and lower strata are well defined even by the outward features; a marked difference appearing in the vegetation and general aspect. The Upper Chalk has usually layers of flint nodules occurring at regular intervals, and is softer than the Lower Chalk. At Sandown Bay, in the Isle of Wight, the latter stratum is defined by a layer of distant and insulated flints which separates it from the Flinty Chalk above; it is sometimes of a grayish colour, as is also the bed of Marly Chalk immediately beneath it. This Marly Chalk is of a tenacious nature, and sustains the water which descends through the Chalk; in consequence, a line of ponds has been produced along the bottom of the escarpment of the South Downs. The Malm-Land, remarkable for its fertility, is the soil over the lowest beds of Marly Chalk. The Malm-Rock, immediately below the Marly Chalk, consists of stony beds belonging to the Upper Greensand formation. Salisbury Plain, which is more than 25 miles in extent from west to east, and 12 miles from north to south, is occupied by the Upper Chalk. Though it has many inequalities of surface, it would be almost destitute of water but for the Avon and its branches, which traverse it. But in the tracts occupied by the Lower Chalk, and still more in the Chalk Marl, there are few valleys without streams; hence, as well as owing to the difference of soil, the vegetation differs also, and the luxuriance of the lower regions affords a strong contrast to the barrenness of the higher downs. The village of Dunstable stands on the Lower Chalk, which may be distinctly traced from Totternhoe through Houghton Regis, Upper Sundon, and Streatley.

Accurate measures of the entire thickness of the Chalk have rarely been made in England. The following are however approximate numbers taken from the best authorities. Sir Henry De La Beche's estimate of the average thickness of this stratum is 700 feet. Dr. Conybeare considers it to range from 600 to 1000 feet. The height of the cliff at Beachy Head, which at the summit includes part of the Flinty Chalk, and goes down very nearly to the Upper Greensand, is only 535 feet; 350 feet is the thickness of the Flinty Chalk at Dover. If then 250 feet are added for the remainder of that division at Beachy Head the aggregate thickness of the chalk on the Sussex coast may be estimated at about 800 feet. At Wendover Hill the total thickness of chalk is considered something more than 500 feet. At Diss, in Norfolk, it was found by boring to be 510 feet. The great variation in thickness is ascribed in part to the unequal removal and abrasion of the upper strata, and in part to the original inequality in the thickness of the Chalk itself.

Greensand.—The general position of this stratum has been sufficiently indicated in describing the boundary of the Chalk, the former outcropping round the latter in an uneven line, in some places much wider than in others.

The Upper Greensand commences immediately on the north of Copt Point, beyond Folkstone, where the succession of the various beds of the system is best seen. Here the Upper Greensand is of comparatively small thickness, and occupies a very narrow belt round the Chalk, running in a west-north-west and then in a westerly direction, as already defined in describing the chalk boundary. It assumes a new character near Godstone, and is there more distinctly marked. The firestone obtained in that part of the country is in the Upper Greensand, occupying four beds separated by seams of stratification; the thickness of the first two beds is respectively 1 foot 9 inches and 1 foot 4 inches; the two others are only 10 inches each. This stone is extensively quarried between Godstone and Reigate. Continuing still in a narrow belt to Guildford, the Upper Greensand forms a slight projection along the foot of the Hog's Back; from Farnham by Selborne and Petersfield to the south of Petworth, this stratum runs out beyond the foot of the chalk-escarpment like a step or terrace. Near Petersfield it is remarkable for its width, which is there 2 miles, a much greater extent than at any other part. A little east of Petersfield, for a short space, this stratum entirely disappears; it then continues in a narrow belt along the north escarpment of the South Downs. This formation is but partially disclosed along the base of the central ridge of Chalk in the Isle of Wight, but it is distinctly seen along the escarpments of the Under-Cliff; its step-like projection beyond the Chalk, as seen in Western Sussex, is likewise observable here in several places.

In the Isle of Purbeck the Greensand runs in a narrow band on the south escarpment of the Chalk, but there the separation of the Upper and Lower Greensands has in a great measure disappeared, and the latter is greatly reduced in thickness or wholly united with the Upper Greensand. The Black Down Hills, in Devonshire, are composed of Greensand; the two beds thus united wanting the intermediate Gault. These hills are distinguished by the uniform level of their summits; and, when cursorily viewed, appear to be composed of horizontal or nearly horizontal beds of Greensand, with here and there an occasional patch of Chalk. It is found however that the rocks composing these hills have been fractured subsequently to their deposition, and that the valleys mostly are lines of faults having a general northerly direction. At some parts there are faults which do not form valleys. In a section across a southern part of the hills the Chalk and Greensand seem to form a continuance; Greensand being on one side of a vertical section, and Chalk on the other. In the yellowish sand, near the surface, at the Barnscombe side of the Beacon Hill, brown iron ore is found in polished fragments of very high lustre. Whetstones are obtained from the Black-Down Hills, the manufacture of which occupies a great number of the neighbouring inhabitants. The quarries are driven in direct lines into the hill, almost horizontally, about 80 feet below the top of the hill. The stones from which the whetstones are cut are irregular concrete masses, imbedded in a looser sand, and more properly belong to the Lower Greensand stratum; but the different strata of the Greensand of these hills are not distinguished by Dr. Fitton, as the Gault between the Upper and Lower Greensand is entirely wanting. The Upper Greensand is not distinctly marked in the great south-western escarpment of the Chalk till beyond the Stour, from the north bank of which it extends northward for about 10 miles to Shaftesbury, and continues thence round the Vale of Wardour. On the south side of the Vale of Wardour the upper beds of this stratum are concealed at the foot of the chalk-hills, but the lower beds shoot out into plateaus, which form the tops of the hills all the way from Shaftesbury along the south side of the Vale of Wardour. On the north side of the vale, the whole series of the Upper Greensand rises abruptly and forms a narrow ridge of unequal height. At the north of the valley this stratum appears to consist of two portions: that which immediately succeeds the Chalk is the same as the firestone of Surrey; the other is equivalent to the Malm-Rock of Sussex, and abounds in chert. In a well sunk at Ridge the Upper Greensand is distinguished into four different strata, their aggregate thickness being 100 feet. The Upper Greensand is not nearly so conspicuous inland as near the coast; from the Vale of Wardour it does not occur again till the Vale of Pewsey. The town of Devizes stands upon a platform of the Upper Greensand, which is there about 430 feet above the sea. It occurs again at Swindon, and then at Tetsworth, whence it continues in a narrow belt and in a north-east direction beyond Cambridge.



The Upper Greensand consists in some places of a soft marly sand, traversed in every direction by stem-like cylinders, having within them cores of darker green matter; it also contains some irregular masses of a bright brown or orange hue, but the greater part is composed of gray calcareous marl, resembling the lowest chalk, but so thickly interspersed with green particles as to entirely assume their colour. The green particles, according to analysis, are found to consist of—

Potash	traces
	98·3

The thickness of this series near Folkstone is from 25 to 30 feet: at Godstone it increases considerably, and the depth of the wells sunk through it in the Malm-Rock strata of Hampshire varies from 60 to 100 feet. In Western Sussex the thickness is between 70 and 80 feet. It is about 70 feet in the Isle of Wight. The thickness of the Greensand at Black Down is about 100 feet, probably from 60 to 80 feet in the Vale of Wardour, and from 30 to 50 feet near Swindon. At Cambridge it is not more than 18 inches; thence through West Norfolk the stratum is nowhere distinctly seen. At Hunstanton the beds which are supposed to represent it are not more than 2 feet thick.

Gault.—The stratum which is usually found between the Upper and Lower Greensand is obscured at East Weare Bay by the ruins of the superior beds, but is visible in detached points. Farther on, towards Folkstone, it becomes more marked, and forms the greater part of the cliff at Copt Point, as well as the grassy cliff between the base of the Martello tower, situated in the vicinity, and the sea. Thence it forms a narrow band between the Upper and Lower Greensand. Near Godstone it occupies a tract distinguished as 'the Black Land,' and forms a slight depression below the stratum which affords the firestone. Between Farnham and Alton this narrow belt of Gault swells out to three or four times its former width, and then again narrowing, continues to form a narrow band between the two strata of Greensand as far as Beachy Head. In the Isle of Wight this stratum likewise forms a narrow band between the Upper and Lower Greensand. The Gault again appears in the Vale of Wardour: on the south it forms a rapid slope; on the north a depression immediately below the sand. It is here identified with that in the eastern counties by the characteristic fossils. At Ridge, near Fonthill Park, the clay of this stratum has been long used for tile-making, and it is there 75 feet in thickness. From the Vale of Wardour, and thence north-eastward to the sea at Hunstanton, the Gault everywhere appears, though it is much reduced in quantity in Norfolk. This stratum occupies a large part even of the higher grounds between Whitchurch and Wing. Immediately to the west of Hitchin and Baldock it is still wider; the towns of Shefford and Biggleswade stand on it. From Cambridge, for a few miles towards the north, it likewise occupies as great a width. In consequence of the numerous borings for water made in Cambridgeshire about this part, its relations and thickness have been well ascertained, especially from Basingbourne through Meldrith, and thence towards Cambridge. This stratum is very distinct at Mildenhall: the Blue Gault has been traced as far as West Newton, about three miles south of Ingoldsthorpe. The valley between the Chalk and Lower Greensand is there interrupted by an advance of the Chalk; and beyond that point the Blue Gault is no longer observable: its place is thence occupied by the red marly stratum of Hunstanton Cliff, which is a calcareous argillaceous matter, 4 feet thick, and it is questioned by geologists whether the term Gault should be applied to it. The Gault, as far as regards its composition, may be divided into two portions: the upper part, immediately succeeding the Upper Greensand, contains green particles, and thence for some feet downwards it is harsh and sandy. The lower portion consists of a smooth uniform very plastic clay, of a light-bluish colour, which is used for tiles and common pottery. Throughout the Gault, but chiefly in the lower part, concretions of iron pyrites are found, and other nodules and irregular masses. The thickness of this stratum at Copt Point is about 130 feet. At Merstham it is 150 feet thick, which is likewise the average thickness in Cambridgeshire. In the Isle of Wight it is about 70 feet; at Ridge about 75 feet; near Thame 90 feet; at Mildenhall the blue clay is only 9 feet. Mr. Rose considers it not more than 15 feet in West Norfolk.

The Lower Greensand.—This stratum appears of a uniform surface, shooting out beyond the Chalk in the south-east counties, and occupies a much larger area than either of the upper strata of the Greensand series. The resemblance in the aspect of the surface of the country, here occupied by the Lower Greensand, to that of the Black-Down Hills, in Devonshire, is extremely striking; and perhaps indicates that the description of the latter more properly belongs to this section than to that which treats of the Upper Greensand stratum. The Lower Greensand has three distinct subdivisions, clearly defined in most parts where it occurs. This series of strata rises gradually from Copt Point, and occupies the whole cliff west of the village; thence it is continued without interruption through Sandgate, and in the heights above Hythe. Its outcrop turns from the coast to the interior at Adlington Corner; here the subdivisions are all distinctly marked, and their respective limits defined. The lower beds, which contain much calcareous matter, are extensively worked in quarries, both for building and lime-burning, at Pluckley, on the north-west, and at Great Chart, on the south-west of Ashford; and generally along the outcrop west of Adlington Corner, where it forms a prominent ridge adjoining the valley of the Weald: here are the principal beds of stone known under the name of 'Kentish Rag.'

Extensive quarries are worked at Boughton, to the south of Maidstone. The stone for the construction of Westminster Abbey is said to have been procured here. The stone is a variety of the Kentish Rag. From Adlington Corner the Lower Greensand continues towards the west in a broad band varying in width; on the coast the distance from the Chalk at Folkstone Hill to the outcrop of this series is about 10 miles, but from Lenham to the outcrop it is not more than 2 miles. Maidstone, Sevenoaks, Godstone, Reigate, Dorking, and Godalming stand on the Lower Greensand series. Near Godstone the surface is comparatively lower, and ponds are frequent where the middle stratum occurs; the stony beds of the lowest group then rise to form the escarpment of Tilburstow Hill, which is nearly on a level with the Chalk Downs. At the top of the hill, the beds, which to the north of Tilburstow Hill rise uniformly at an angle of not more than 10 degrees, are suddenly thrown up to about 45 degrees, giving decisive evidence of an elevation from the Chalk, or of a sinking towards it. Fullers' Earth has been dug in this part of Surrey for a very long period; at present the neighbourhood of Nutfield is the only place in which it is got. The beds occur near the top of the lowest stratum of Greensand; in one pit near Nutfield the principal bed of Fullers' Earth is 16 feet thick. On the south of the Hog's Back the Lower Greensand rises, like the Chalk, at a very high angle, and then, being bent suddenly in an opposite direction, is continued several miles to the south. Hindhead is the most prominent point in this part of the country, where the whole of the tract occupied by the Lower Greensand is wild and barren, producing only fern, heath, and furze.

As this formation turns towards the east and continues along Sussex to the coast, it is not nearly so wide as on the north of the Weald. At Beachy Head it is three miles wide, but it is only one mile wide a little to the west of the spot where the Adur runs through it. The Lower Greensand occupies a great part of the surface on the south of the Isle of Wight, and is everywhere conformable to the Chalk, a ridge of highly-inclined strata of Greensand crossing the island from the shore on the south of Bembridge-Down to the foot of Afton Down. The sands likewise form the lower ground of the interior from Mottestone through Newchurch to the coast.

A narrow belt of Greensand runs along the west and north-west of Dorsetshire. In the Vale of Wardour the Lower Greensand is nowhere prominent; but it occupies the whole of the entrance of the Vale of Pewsey, and continues with its subdivisions well defined through the northern counties in a north-east direction as far as the coast of Norfolk. The greatest width of the formation in this part occurs between Leighton and Ampthill in Bedfordshire, where it rises in Bow-Brickhill to the height of 683 feet above the sea. Near Woburn there is a fullers' earth pit, the beds of which occur, like those in Surrey, near the top of the lowest division; that of the best quality is in a bed from seven to nine feet thick. The pits in this part of the country have continued to supply fullers' earth for more than a hundred years.

The three groups into which this stratum is divided are, in most places in the south-east counties where sections have been made, well defined; and in general, in different situations where this formation occurs, the respective characteristics are found to be alike. The Cretacean System is not confined to England, but is found extending over very large portions of the continent of Europe. It is seen in France on the coasts opposite to England, and it is found on the north as far as Denmark. It may in fact be traced from the north-east of Ireland to the borders of Asia Minor, and from Denmark to the south of France. It also has its representative in some parts of North America. In South America deposits of this period have also been developed along the whole country from Columbia to Tierra del Fuego. The south-east of India has also yielded fossils, which apparently belong to this period.

The organic remains in the Chalk and Greensands are usually abundant, and are mostly marine. They consist of marine plants: *Infusoria*, Sponges, Zoophytes, *Echinodermata*, *Mollusca*, *Crustacea*, Fishes, and Reptiles. Sir Henry De La Beche observes, that "Organic remains are in general beautifully preserved in the chalk; substances of no greater solidity than common sponges retain their forms, delicate shells remain unbroken, fish even are frequently not flattened, and altogether we have appearances which justify us in concluding that since these organic exuviæ were entombed they have been protected from the effects of pressure by the consolidation of the rock around them, and that they have been very tranquilly enveloped in exceedingly fine matter, such as we should consider would result from a chemical precipitate."

The most remarkable form in which the fossils of this formation appear is that of flint. The production of this substance has by some been referred to organic agencies. [FLINT.]

Although the remains of plants are rare in this formation in England, they have been found in abundance in the contemporaneous sandstones of the continent of Europe. Amongst them have been found the remains of dicotyledonous plants.

An examination of the flints by the microscope reveals the existence of many forms of *Diatomaceæ* in the Chalk. From the siliceous structure of their frustules these organisms are entirely preserved wherever they occur. A large number of species have been discovered in the Chalk. [DIATOMACEÆ.]

Amongst the lowest animals we must now reckon the *Foraminifera*, which were formerly regarded as minute *Cephalopoda* by D'Orbigny. Many forms of these creatures, which seem to hold a place between the Sponges and some of the *Infusoria* are found in the Chalk. [Foraminifera.]

Of the Zoophytes, the *Polyzoa* have been found in the greatest abundance in the Cretaceous beds (*Neocomien*) of the continent of Europe. They have been most elaborately described by D'Orbigny. [Polyzoa.]

The *Echinodermata* abounded during the period of the deposit of the Chalk, and afford a larger number of interesting forms than occur in any other formation. The genus *Marsupites* affords an instance of the passage amongst these creatures from *Encrinites* to the *Spatangi*. Numerous species of *Spatangus*, *Cidaris*, *Goniaster*, and other genera of this family are found. The spines of the *Echinidæ* are often found separated from the shell. [Echinodermata.]

Several forms of *Crustacea* belonging to the more highly-developed sections of the family are found.

The *Mollusca* are abundant. Of these the forms of *Brachiopoda*, especially *Terebratula*, are numerous. The genus *Rudistes*, which D'Orbigny refers to the *Brachiopoda*, is in some respects the most interesting of the *Mollusca* of the Cretaceous Formations. The species are most abundant in the Cretaceous series of the South of Europe. The Cephalopodous *Mollusca* were very numerous and varied in their forms during the Cretaceous period. The following genera are found:—*Nautilus*, *Ammonites*, *Crioceratites*, *Turrilites*, *Scaphites*, *Baculites*, *Hamites*, and others.

The Fishes of the Cretaceous system are numerous, and belong to the Placoid, Ganoid, Ctenoid, and Cycloid types. Of the last two the genera are fewer in number than of the first two. The Ctenoids and Cycloids however appear in the Cretaceous system for the first time, and are interesting on this account.

The Reptiles, though not so numerous in the Cretaceous period as in that which immediately preceded it, are nevertheless numerous. It is here that the *Mososaurus* has been found, also several species of *Pterodactyli*, and the remains of the *Iguanodon* and *Ichthyosaurus*, with species of *Chelonia*.

CHALYBÆUS, a genus of Birds, separated by Cuvier from the Cassicans of Buffon; *Barita* of Cuvier. The bill has the same form as that of the Cassicans, but it is a little larger at the base than that organ is in the last-named genus, and the nostrils are pierced in a large, membranous space.

The species come from New Guinea, and are remarkable for the metallic tints of their plumage.

Example, *Chalybæus paradisæus*. This richly-plumed bird is the *Paradisea viridis* of Gmelin; Le Calybé de la Nouvelle Guinée of Buffon; Le Grand Chalybé of Le Vaillant; Oiseau de Paradis Vert of Sonnerat; *Paradisea chalybea*, Blue-Green Paradise Bird, of Latham; *Cracticus chalybeus* of Vieillot; *Barita viridis* of the first edition of the 'Règne Animal' (where it was placed under the Cassicans, *Barita*), and *Chalybæus paradisæus* of the last edition. It is the Mansinème of the Papuan tongue, according to Lesson, who thus writes on the subject from personal observation:—"Among the numerous skins of birds of paradise which the inhabitants of New Guinea brought daily on board, I found some *Chalybæi* deprived of their feet, and run through with a stick like the skins of the true birds of paradise. Afterwards we often procured in our shooting parties a bird which does not vary from that of which we speak, except in having a more sombre and tarnished plumage, there being no difference in the proportions of the body, bill, wings, or tail. We regard it as a slight variety of the Calybé of authors; for those that we saw which were adult and in complete plumage, did not permit us to think that they could be *Chalybæi* before or after their moult. The total length of our *Chalybæus* was 14 inches 6 lines (French). The bill differed not at all from the ordinary *Chalybæus*. The head is large, and the tail, 6 inches in length, is rounded by the disposition of the feathers, as in the preceding. The plumage is entirely bluish metallic green, having none of the iridescent, varying, and violet tints. The feathers of the neck and abdomen are not figured (gaufrées), nor powdered (sablées) with gold and silver on a green and blue ground of burnished steel, as it were (d'acier bruni), like the *Chalybæus*; but the plumage that covers these parts has a uniform tint, having the brilliancy of specular iron (fer spéculaire) following the reflections of the light. The feathers which cover the head and neck are short, close set, and velvety. The nostrils are partially closed by a membrane covered by the frontal feathers, which advance on each side of the edge (arête) of the bill, which is black. The iris is coral-red, and the legs are of the same colour as the bill. Their shanks (tarses) are covered with large scales (écussons), and their toes are strong, furnished with compressed claws, flattened above, and crooked.

Blue-Green Bird of Paradise (*Chalybæus paradisæus*).

"The *Chalybæus* lives solitary in the forests of New Guinea. We often saw it perched in the great trees, where it seeks for fruits. Its manners appeared to have great analogy to those of the crows."

CHALYBEATE WATERS. The water of springs charged with any of the salts of iron are called Chalybeate. [Springs, Mineral.]

CHAMA. [Chamacea.]

CHAMA'CEA, or CHA'MIDÆ, a family of Conchiferous *Mollusca*, the third of the Acephalous or Headless *Testacea*, according to Cuvier, who places them between his *Mytilacea* (Mussel-like Testaceans), and his *Cardiacea* (Cockle-like Testaceans).

Under the Linnæan genus *Chama* many heterogeneous forms were assembled; and as G. Sowerby observes, "in his arrangement regular and equivalve shells are placed with such as are irregular and equivalve; free shells with others that are attached to marine bodies; and shells which have two distinct muscular impressions with others which have only one."

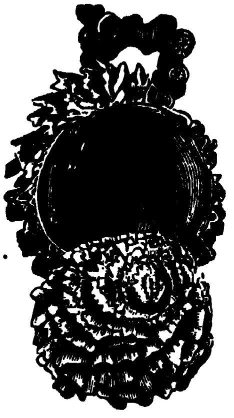
Bruguière first divided this genus, and Lamarck carried out the reformation. The latter makes the *Chamidæ* to consist of the genera *Diceras*, *Chama*, and *Etheria*, placing *Tridacna* and *Hippopus* under his Tridacnées, the first section of his second order Conchifères Monomyaires.

Cuvier made the Camacées consist of the genera *Chama*, *Tridacna*, *Hippopus*, *Chama* (Brug.), *Diceras*, and *Isocardia*.

The genus *Chama* has the following characters:—The valves are irregular, inclining for the most part to the orbicular shape, unequal, generally foliated or spined externally, and adherent. The umbones are distant, unequal, and curled or involute. The hinge consists of one thick oblique somewhat notched tooth, inserted into the groove of the opposite valve. There are two muscular impressions, and they are distant and lateral. The ligament is external, and divided into two portions at its posterior extremity. The animal (*Psilopus* of Poli) is less irregular than the shell, and cordiform, or heart-shaped; the two lobes of the mantle unite posteriorly, and in the commissure are two very short ciliated siphons, like those of *Isocardia*. Upon the abdominal mass a small cylindrical truncated bent foot rises. The mouth is small, and is furnished on each side with a pair of somewhat square and obliquely-truncated palpi. Deshayes states that all the individuals of the same species adhere by the valve of the same side, and that the umbones curve in the same direction.

Broderip, in the first volume of the 'Transactions of the Zoological Society of London' (1834), where he describes several new species brought home by Mr. Cuming, says, "The shells are attached by their external surface to submarine bodies, such as corals, rocks, and shells, and have been observed at depths ranging from points near the surface to 17 fathoms. These shells appear to be subject to every change of shape, and often of colour, that the accidents of their position may bring upon them. Their shape is usually determined by the body to which they are fixed; the development of the foliated laminæ which form their general characteristic is affected by their situation; and their colour most probably by their food and by their greater or less exposure to light. The *Chama* that has lived in deep and placid water will generally be found with its foliations in the highest state of luxuriancy; while those of the individual that has borne the buffeting of a comparatively shallow and turbulent sea will be poor and stunted. Lamarck has divided the species into two sections, namely, first, those the umbones of whose shells turn from left to right; and, secondly, those whose umbones turn from right to left. M. Sander Rang, in his 'Manual,' has adopted this division, to which I cannot subscribe, because it will not bear the test of examination. Two remarkable instances are now well known of regular bivalves of the same species, in which one specimen may be regarded as being the reverse of the other, namely, *Lucina Childreni*, and an inequivalve

Mytilus in the British Museum: and to come at once to the case before us, the same species of *Chama* is sometimes attached by the right, sometimes by the left valve; or, in other words, in one individual of the species the umbones will turn from left to right, while in another individual they will turn from right to left." The same author observes, that the distinction of the species appears to him to be difficult, the variety being infinite. The number of recent species given in Deshayes's edition of Lamarck (1835) is seventeen, including *Chama albida* (Camostrée of De Roissy; *Cleidothærus* of Stutchbury). Broderip, in the paper above alluded to, describes eleven additional species with varieties not noticed by Deshayes, who has however some observations on the following species, *C. Lazarus*, *C. gryphoïdes*, *C. unicornis*, *C. asperella* (the living analogue of *C. echinulata* in Lamarck's fossil list), and *C. albida*, well worthy the attention of the student. We elect as an example *C. gryphoïdes* (*C. gigas*, Linn.), which is famous for its enormous size. Individuals have been known to weigh above three hundred pounds. The byssus by which it adheres to rocks is so tough that in order to procure the shell it must be cut with an axe. The animal may be eaten, but its flesh is very tough. Some very large specimens are to be seen in the Gardens of the Zoological Society, Regent's Park. One of the valves is sometimes used as a font for baptism in country churches.



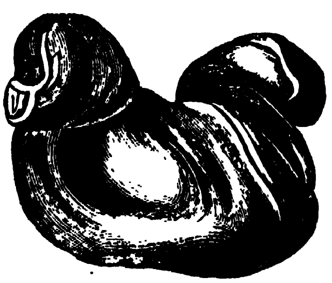
Chama gryphoïdes.

The species are apparently confined to the warmer seas, the Mediterranean being the locality of the lowest temperature where any of them have been hitherto found.

Fossil Chamidæ.

The fossil species of *Chama* are numerous, and occur in the supracretaceous groups, particularly in the subappenine beds, and those of Bordeaux and Dax; in the Cretaceous group; and also in that of the Oolite. According to G. B. Sowerby, they are found in the London Clay, and Calcaire Grossier, also in the Chalk and Greensand. Deshayes, in his tables, gives fifteen living species, and twenty fossil (tertiary), occurring in the Pliocene, Miocene, and Eocene periods. Of these he makes four, namely, *C. gryphoïdes*, *C. crenulata*, *C. sinistrorsa*, and a new species, both living and fossil; the localities for the living (with the exception of *crenulata*, from Senegal) being the Mediterranean Sea. The species found in more than one Tertiary formation he makes *C. echinulata*, *C. rustica*, and *C. lamellosa;* and gives the following number of species in the localities here mentioned:—Four in Sicily, four in Italy (subappenine beds), one at Bordeaux, three at Dax, three in Touraine, two at Vienna, two at Angers, nine at Paris, one at London, and two at Valognes. In the fossil list of his edition of Lamarck (1835), Deshayes enumerates only thirteen fossil species, and of these he makes *C. gryphina* include *C. sinistrorsa* as a synonym, observing in a note that he knows the living analogue as existing in the Sicilian seas, and that the species No. 3 (*C. lacernata*) is a variety of this, while the valves cited as belonging to the environs of Angers belong to another species. *C. echinulata* he identifies with *C. asperella* now living in the Mediterranean. *C. unicornaria*, he observes, was formed for a variety of *C. gryphina*, with very large umbones; and he suggests the necessity of uniting *C. gryphina*, *C. lacernata*, and *C. unicornaria* in one species. Nilsson names *C. cornu Arietis* (*Diceras arietina ?*), Kjuge; Morby, Sweden; and *C. laciniata*, Kjuge; Balsberg; Morby, Sweden; and Mantell, an undetermined species from the Chalk, Sussex. Phillips names *Chama mima*, or *Gryphæa mima* (the genera are sufficiently different, by the way), from the Coral Oolite and Calcareous Grits of Yorkshire. Smith, *Chama* (?) *crassa* from the Bradford Clay. Thurman, *C. Bernojurensis*, from the Calcareous Grit, Bernese Jura; and Lonsdale, an undetermined species from the Cornbrash Forest Marble, and Bradford Clay, Wilts.

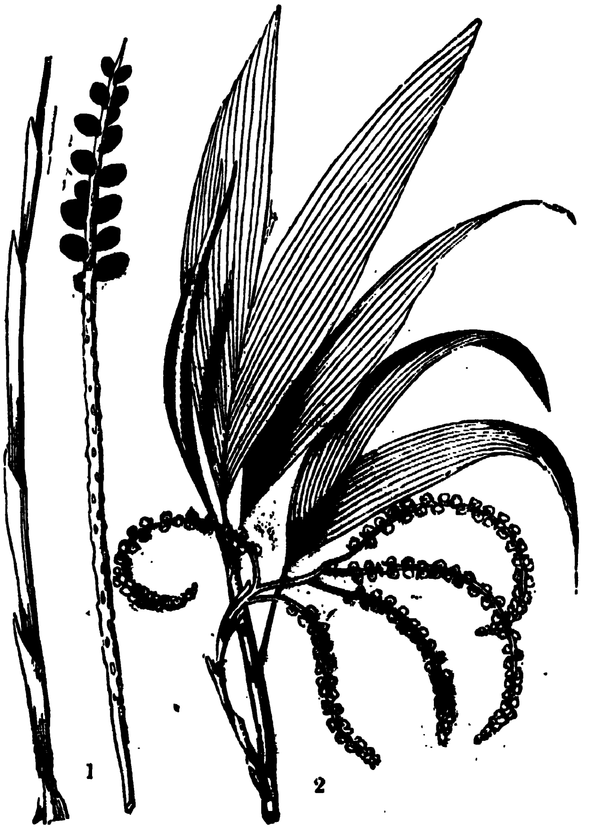
Cuvier says that the *Dicerata* do not appear to differ from the *Chama* in anything essential; only their cardinal tooth is very thick, and the spirals (umbones) of their valves are sufficiently projecting to remind the observer of two horns. G. B. Sowerby thus writes: "On account of the similarity between this genus (*Chama*) and *Diceras* we shall be expected to explain the characters by which this latter is distinguished from *Chama*, with which indeed it is arranged by Bruguière; these, according to Lamarck, are the large, conical, diverging, spiral umbones, and the large, concave, subauriculate, prominent tooth in the large valve of *Diceras*. Not having ourselves seen the hinge of *Diceras*, we will not venture to offer an opinion; but, judging from the specimens we possess, we see in *Diceras* a sort of connecting link between *Isocardia* and *Chama*, having both the umbones free and involute, and being moreover a nearly equivalve shell, like *Isocardia;* but being attached by one valve, and not quite equivalve, in these respects resembling *Chama*." Rang observes: "This genus is very imperfectly known, without doubt, but nevertheless one may well believe that it is very near to *Chama*." Defrance enumerates five species. Deshayes does not give it as a genus in his tables, and in his last edition of Lamarck only two species are recorded, *Diceras arietina* (Lam.), the type from Mont Salève and the neighbourhood of St. Mihiel, and *Diceras sinistra* (Desh.), from the superior Oolite in the vicinity of the last-named place.



Diceras arietina.

Rang would place next to *Diceras* the genus *Caprina* of D'Orbigny senior; and he is of opinion that if that zoologist would publish his discoveries on these interesting shells, the genus would be generally adopted. The genus *Ichthyosarcolite*, which has been always classed with the Cephalopods, might, he thinks, belong to a bivalve approximating to *Caprina*. Deshayes, he says, communicated to him the same idea. But the last-named author does not notice the genus when treating of *Diceras* in the last edition of Lamarck.

CHAMÆDO'REA, a genus of Palms, also called *Nunnezharia* and *Nunnezia*. They are small reed-like plants, with ringed shoots. Their leaves are either cleft or pinnated. The inflorescence is sessile within the sheaths of the leaves, and branched in an irregular manner; the spathes are membranous. The flowers are yellow and diœcious, without bracts, which is a remarkable circumstance. In the males the calyx is cup-shaped and 3-parted, the petals 3, and the stamens 6. In the females the calyx and petals are the same; the ovary 3-celled; the berry 1-seeded; the albumen even; and the embryo lateral. These are palms of humble growth, receding in that respect from the general character of the order, and approximating to Herbaceous Endogens, or to Bamboos. *C. fragrans*, the Chutasslium of the Peruvians, is a plant with a stem about a man's height, and so fragrant as to fill the groves with its perfume in the months of August, September, and October.



1, *Chamædorea pauciflora;* 2, *C. fragrans.*

CHAMÆLAUCIACEÆ, Fringe Myrtles, a small natural order of Polypetalous Exogenous Plants. They are characterised by having a 1-celled ovary, ascending ovules, dotted leaves, and the embryo fused into a solid mass. They are small bushes with evergreen leaves, and in external appearance have a close resemblance to heaths. All their parts abound in glandular oily cavities. They are mostly regarded as belonging to *Myrtaceæ*, and there is no doubt of their affinity to that order. Their peculiar aspect, abortive stamens, simple ovary, and pappose calyx sufficiently distinguish them. They have the fragrance of *Myrtaceæ*. Fifteen genera and fifty species are included in this order, all natives of Australia. Their position, according to Lindley, is between *Asteraceæ* and *Combretaceæ*, near to *Myrtaceæ*. (Lindley, *Vegetable Kingdom*.)

CHAMÆLE'DON, a genus of plants belonging to the natural order *Ericaceæ*. *C. procumbens* is a beautiful little alpine bush, formerly referred to *Azalea*, from which it differs essentially both in habit and botanical characters. It is a small evergreen creeping shrub, found on the mountains of Europe and North America. The leaves are leathery, shining, turned back at their edge, and about half an inch long. The flowers are minute, and grow in terminal umbels of a light flesh-colour. The calyx is 5-parted; the corolla campanulate and regularly 5-cleft, the anthers rounded and opening longitudinally. It is occasionally seen in gardens, but it is rather impatient of cultivation.

CHAMÆLEONIDÆ. [CHAMELEONS.]

CHAMÆPELIA. [COLUMBIDÆ.]

CHAMÆ'ROPS, a genus of Palm-Trees, in which is comprehended the most northern species of those remarkable vegetable productions whose home is so frequently in the tropics. It is characterised by its flabelliform leaves, polygamous flowers, which are sometimes even diœcious, and triple monospermous drupes, with ruminated albumen. *Chamærops humilis*, the European species, grows in hot-houses to the height of 15 feet; but in Spain and Barbary it is not more than 4 or 5 feet high, and in Italy it is much dwarfer. It is common upon the hills near Algiers. It occurs in many places in the southern parts of Italy, and reaches its northern limits in the vicinity of Nice. The trunk of this plant is 5 or 6 inches in diameter, and closely covered with triangular hard scales, which are the bases of the old leaves. The new leaves grow in a tuft at the top of the stem, and have smooth flat stalks, with rigid spines proceeding from the edge; the blade is deeply palmate, with from 12 to 15 narrow sword-shaped divisions, which are slightly glaucous and downy. The flowers grow within compressed spathes, which are downy at the edge, and from 6 to 8 inches long, and upon a short compressed spadix, which is closely covered over. The drupes are blackish-brown, and round, with a fibrous dry spongy flesh. The young underground parts of the stem and the young roots are said by Desfontaines to be eatable.

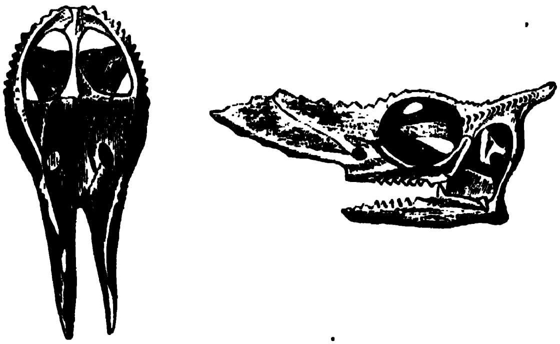
European Palm (*Chamærops humilis*).

CHAMÆZA, a genus of Birds belonging to the family *Merulidæ* of Vigors. [MERULIDÆ.]

CHAMECK. [ATELES.]

CHAMELEONS, CHAMELEON-TRIBE, CHAMÆLEONIDÆ, the name for a well-defined family of Saurians (Lizard-like Reptiles), whose differential and essential characters may be summed up as existing in the form of their feet, the toes of which are joined or bound up together in two packets or bundles opposed to each other—in their shagreen-like skin—in their prehensile tail—and in their extensile and retractile vermiform tongue.

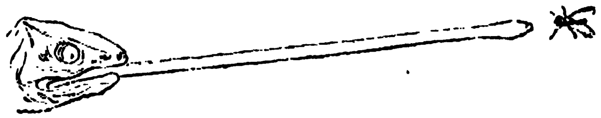
Organisation.—Skeleton.—The more striking peculiarities consist in the elevated and pyramidal form of the occiput; the absence of a true sternum; and in certain apophyses of the vertebral column, especially about the tail, where they are placed en chevron, so as to leave at their base a space where the caudal artery, a prolongation of the pelvic, is protected somewhat in the same way as the spinal cord is by the bony case above it, when the prehensile tail would otherwise subject it to pressure in grasping boughs of trees or other solid bodies with its lower surface. The transverse apophyses of the tail are but little developed. The glenoid cavity is supported upon a short pedicle. The majority of Saurians have eight cervical vertebræ, but the Chameleons have only five. The first ribs are joined to the mesial line, which performs the office of a sternum, and the following ribs are united to each other by their cartilaginous prolongations towards the mesial line of the belly, so as to protect the abdomen by an entire bony circle. There are, as Schneider has observed, but two shoulder-bones, of which the coracoid is very small, the clavicle being entirely absent. Cuvier remarked the singular disposition of the wrist. The two carpal bones which come next to those of the fore-arm are articulated upon one large central piece, which receives the five bones which correspond to the metacarpal, three of these being for the external toes and two for the internal, thus forming two opposeable prehensile instruments, the two bundles being bound up in the integuments and skin to the very claws. In the pelvis, the ilia are long and slender and directed towards the sacrum, with which they partially unite, but are prolonged by a cartilage. The hind as well as the fore toes are five, and disposed in the same manner as those of the anterior extremities. The trunk, which has a compressed appearance, is mounted high on the legs, forming an exception to the majority of reptiles, whose belly touches the ground.



Skull of *Chamæleo bifidus*.

Organs of Respiration.—Cuvier observes that their lung is so large that when it is filled with air it imparts a transparency to the body, which made the ancients say that it lived upon air; and he inclined to think that to its size the Chameleon owed the property of changing its colour. But with regard to this last speculation he was in error, as we shall presently see.

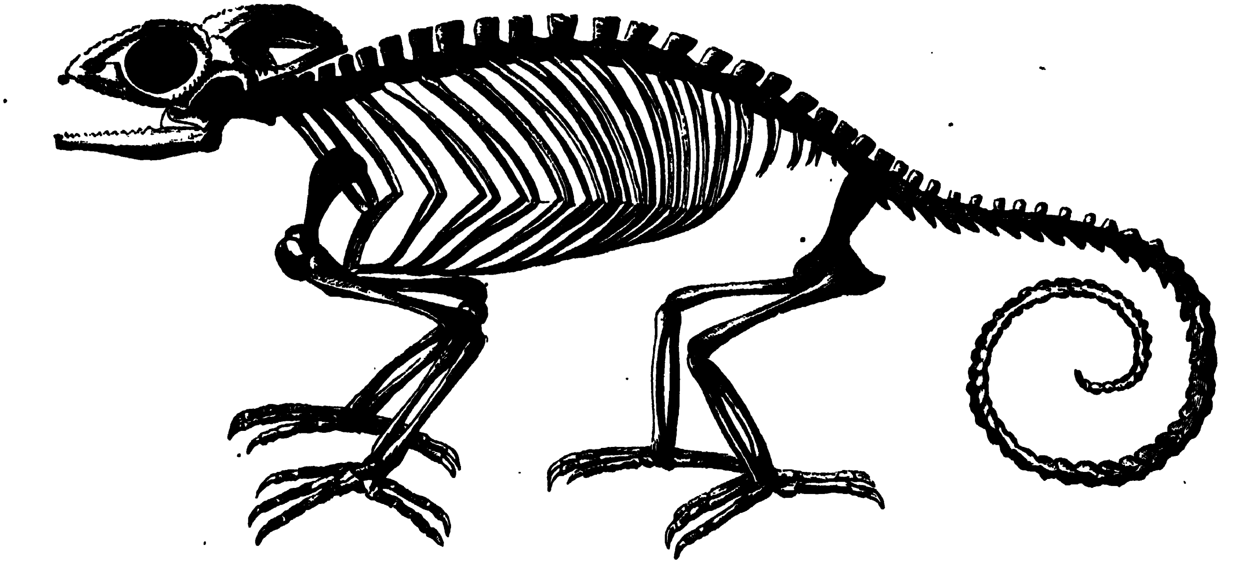
Organs of Nutrition and Digestion.—The teeth, as in the great majority of Saurians, have no true roots: their crowns, which are trilobated, seem to be soldered as it were upon the edge of the upper border of a groove hollowed in the maxillary bone; they are connected to the osseous portion and also to each other, so as to present the appearance of an enamelled and denticulated portion of the edge of the bone. But it is the vermiform extensile and retractile tongue which is the chief organ for taking the insects on which the chameleon lives. By a curious mechanism, of which the os hyoides (tongue-bone) is a principal agent, the Chameleon can protrude this cylindrical tongue, which is terminated by a dilated and somewhat tubular tip covered with a glutinous secretion, from the sheath at the lower part of the mouth (where the whole of the tongue, with the exception of the dilated tip, remains when at rest) to the length of six inches. When the Chameleon is about to seize an insect it rolls round its extraordinary eyeballs so as to bring them to bear on the devoted object: as soon as it arrives within range of the tongue, that organ is projected with unerring precision, and returns into the mouth with the prey adhering to the viscous tip.



Chameleon taking his prey.

There is not much difference between the œsophagus and stomach, which latter is small and bent back upon itself. There is no true pylorus, although there exists, at the point where it should be, a sort of contraction in the membranes, which are there thickened.

Organs of Sense.—Touch.—On the under surface of the tail and toes are granulated papillæ, probably for the purpose of conveying to the sensorium the nature of the body grasped. The tongue must have a considerable share of the sense of touch; whether it has any high perception of that of taste may be doubted. Smell.—Most probably not acute; the external orifices of the nostrils are more lateral, and consequently wider apart than in most of the other Saurians. Hearing.—There is no visible external ear, but an internal cavity not much developed in the bones of the sides of the skull, communicating with the throat, and covered externally by the common integuments.



Skeleton of Chameleon (*Chamæleo vulgaris.*)

Sight.—The eyes of the Chameleon are remarkable objects; large, projecting, and almost entirely covered with the shagreen-like skin, with the exception of a small aperture opposite to the pupil: their motions are completely independent of each other. It adds to the strange and grotesque appearance of this creature, to see it roll one of its eye-globes backwards, while the other is directed forwards, as if making two distinct surveys at one time. Its sight must be acute, from the unerring certainty with which it marks and strikes its prey.

Reproduction.—By means of eggs, which are numerous at each deposit, oval, and enveloped in a white, tough, parchment-like skin.

Habits, &c.—The Chameleons spend their lives in trees, clinging to the branches by means of their feet and tail. There they lie in wait for the insects which may come within their reach; and it is highly probable that, in such situations, their faculty of changing their colour becomes highly important in aiding them to conceal themselves. They move about with great regularity and a kind of affected gravity. The powers of abstinence possessed by this singular race are very great, and hence most probably arose the old fable of their living on air, which was for a long time considered to be "the chameleon's dish." We kept one for upwards of six weeks, and during all that time it never, as far as we could observe, took any sustenance, though meal-worms and other insects were procured for it. Notwithstanding this fast, it did not appear to fall away much. It would fix itself by the feet and tail to the bars of the fender, and there remain motionless, apparently enjoying the warmth of the fire for hours together. Its motions were excessively slow. It was a female, and died after laying a great number of eggs. Hasselquist describes one that he kept for near a month, as climbing up and down the bars of its cage in a very lively manner. Numbers have been exhibited from time to time in the Zoological Gardens, Regent's Park, but they do not live long. The males are distinguished by the thickness of their tails.

That the Chameleon was known to the ancients there is no doubt. It was the Χαμαιλέων of the Greeks and the *Chamæleo* of the Latins. Aristotle's history of the animal proves the acute observation of that great zoologist, for he notices the peculiarities of the animal, the absence of a sternum, the disposition of the ribs, the mechanism of the tail, the motion of the eyes, the toes bound up in opposeable bundles, &c., though he is not entirely correct in some points. ('Hist. Anim.,' book 2, ch. xi.) Pliny ('Hist. Nat.,' lib. viii., c. 33) mentions it, but his account is for the most part a compilation from Aristotle.

The power possessed by these creatures of changing colour has been a subject of wonder and exaggeration from an early period. Wood, in his 'Zoography,' gives the following translation of the account given by the French academicians of this phenomenon: "The colour of all the eminences of our chameleon, when it was at rest, in the shade, and had continued a long time undisturbed, was a bluish-gray, except under the feet, where it was white inclining to yellow; and the intervals of the granules of the skin were of a pale and yellowish-red. This gray, which coloured all the parts exposed to the light, changed when in the sun; and all the places of its body which were illuminated, instead of their bluish colour, became of a brownish-gray, inclining to minime. The rest of the skin which was not illuminated by the sun changed its gray into several brisk and shining colours, forming spots about half a finger's breadth, reaching from the crest of the spine to the middle of the back; others appeared on the ribs, fore legs, and tail. All these spots were of an Isabella colour, through the mixture of a pale yellow with which the granules were tinged, and of a bright red, which is the colour of the bottom of the skin which is visible between the granules; the rest of the skin not enlightened by the sun, and which was of a paler gray than ordinary, resembled a cloth made of mixed wool; some of the granules being greenish, others of a minime gray, and others of the usual bluish-gray, the ground remaining as before. When the sun did not shine, the first gray appeared again by little and little, and spread itself all over the body, except under the feet, which continued of the same colour, but a little browner; and when, being in this state, some of the company handled it, there immediately appeared on its shoulders and fore legs several very blackish spots, about the size of a finger nail, and which did not take place when it was handled by those who usually took care of it. Sometimes it was marked with brown spots, which inclined towards green. We afterwards wrapped it up in a linen cloth, where having been two or three minutes we took it out whitish; but not so white as that of which Aldrovandus speaks, which was not to be distinguished from the linen on which it was laid. Ours, which had only changed its ordinary gray into a pale one, after having kept this colour some time, lost it insensibly. This experiment made us question the truth of the chameleon's taking all colours but white, as Theophrastus and Plutarch report, for ours seemed to have such a disposition to retain this colour, that it grew pale every night, and when dead it had more white than any other colour; nor did we find that it changed colour all over the body, as Aristotle reports; for when it takes other colours than gray, and disguises itself to appear in masquerade, as Ælian pleasantly says, it covers only certain parts of the body with them. Lastly, to conclude the experiments relative to the colours which the chameleon can take, it was laid on substances of various colours, and wrapped up therein; but it took not them as it had done the white, and it took that only the first time the experiment was made, though it was repeated several times on different days. In making these experiments we observed that there were a great many places of its skin which grew brown, but very little at a time: to be certain of which we marked with small specks of ink those granules which to us appeared whitest in its pale state, and we always found that when it grew brownest and its skin spotted, those grains which we had marked were always less brown than the rest."

Numerous theories, some of them sufficiently absurd, have been proposed to account for this phenomenon. It was reserved for Milne-Edwards to give a complete and satisfactory explanation. In a paper published in the 'Annales des Sciences Naturelles' for January, 1834, and translated in the 17th vol. of the 'Edinburgh New Philosophical Journal,' he has given the result of his investigations. The following are his conclusions:—

1. That the change in the colour of Chameleons does not depend essentially either on the more or less considerable swelling of their bodies, or the changes which might hence result to the condition of their blood or circulation; nor does it depend on the greater or less distance which may exist between the several cutaneous tubercles; although it is not to be denied that these circumstances probably exercise some influence upon the phenomenon.

2. That there exists in the skin of these animals two layers of membranous pigment placed the one above the other, but diposed in

such a way as to appear simultaneously under the cuticle, and sometimes in such a manner that the one may hide the other.

3. That everything remarkable in the changes of colour that manifest themselves in the Chameleon may be explained by the appearance of the pigment of the deeper layer, to an extent more or less considerable, in the midst of the pigment of the superficial layer; or from its disappearance beneath this layer.

4. That these displacements of the deeper pigment do in reality occur; and it is a probable consequence that the chameleon's colour changes during life, and may continue to change even after death.

5. That there exits a close analogy between the mechanism by the help of which the changes of colour appear to take place in these reptiles, and that which determines the successive appearance and disappearance of coloured spots in the mantles of several of the Cephalopods.

This family embrace but the one genus, *Chamæleo.* Dr. J. E. Gray places the *Chamæleonidæ* in the tribe *Dendrosaura,* of the sub-order *Pachyglossæ,* of the order *Saura,* or Lizards. The tribe *Dendrosaura* embrace only this family, and have the following characters:—Scales of the belly, sides, and back, granular. Tongue elongate, sub-cylindrical, worm-like, very extensile. Eyes globular, very mobile, with a small central round opening. Toes equal, united in two opposing groups.

The species are inhabitants of the Old World, in Africa and Asia, and are naturalised in Southern Europe.

The following species are described in the 'Catalogue of the Specimens of Lizards in the British Museum:'—

* Back with an erect fin. Belly crested.

C. cristatus, the Fringed Chameleon. A native of Fernando Po.

** Back high, compressed. Belly and sides with a toothed crest.

C. lateralis, the Side-Crested Chameleon. It is a native of Madagascar.

*** Back and belly with a toothed crest. Sides simple.

† Scales equal, small. Muzzle simple.

C. vulgaris, the Chameleon. It is the *C. mutabilis,* Meyer; *C. cinereus,* Aldrovandus; *C. Parisiensis, C. Zeylandicus,* and *C. Mexicanus,* Laurent; *C. carinatus, C. subcroceus, C. calcaratus,* Merrem; *C. Zebra,* Bory; *Lacerta Chameleon,* Linnæus. It is a native of the East Indies, and the species which is most frequently brought to England.

Chameleon (*Chamæleo vulgaris*).

C. Senegalensis, the Senegal Chameleon. It is the *Lacerta Chameleon* of Linnæus; *C. Bonæ Spei* of Laurent; *L. pumila* of Gmelin. It is a native of the West of Africa.

C. dilepis, the Flap-Necked Chameleon. Found in Africa. Specimens in the British Museum have come from Fantee, Ashantee, Gambroon, and Senegal.

†† Scales unequal, larger tubercles. Muzzle simple.

C. Pardalis, the Bourbon Chameleon. A native of Bourbon.

C. verrucosus, the Warty Chameleon. It inhabits Madagascar.

††† Scales unequal. Muzzle (of male) with a central prominence.

C. Rhinoceratus, the Rhinoceros-Chameleon. A native of Madagascar. Specimens of this and the last species were presented to the British Museum by Sir Edward Belcher.

**** Back with a toothed crest. Belly and sides simple.

† Chin and muzzle simple.

C. tuberculiferus, the Tuberculated Chameleon. A native of South Africa.

C. cucullatus, the Hooded Chameleon. An inhabitant of Madagascar.

†† Chin simple; muzzle compressed, produced.

C. nasutus, the Sharp-Nosed Chameleon. A native of Madagascar.

††† Chin simple; muzzle of male forked.

C. bifurcus, the Large-Naped Chameleon. A native of Madagascar.

†††† Chin bearded; muzzle simple.

C. Tigris, the Fringed Chameleon. Found in the Seychelle Islands.

C. ventralis, the Belly-Shaped Chameleon. Found in South Africa.

C. pumilus, the Pearled Chameleon. A native of the Cape of Good Hope.

***** Back and belly not crested.

C. Parsonii, Parson's Chameleon. A native of Madagascar.

C. Owenii, the Three-Horned Chameleon. It is a native of Fernando Po.

C. Brookesianus, Brookes's Chameleon. Locality unknown. Named from a specimen in the Museum of Joshua Brookes.

CHAMOIS. [ANTILOPEÆ.]

CHAMOISITE, a mineral, composed of Silicate of Iron.

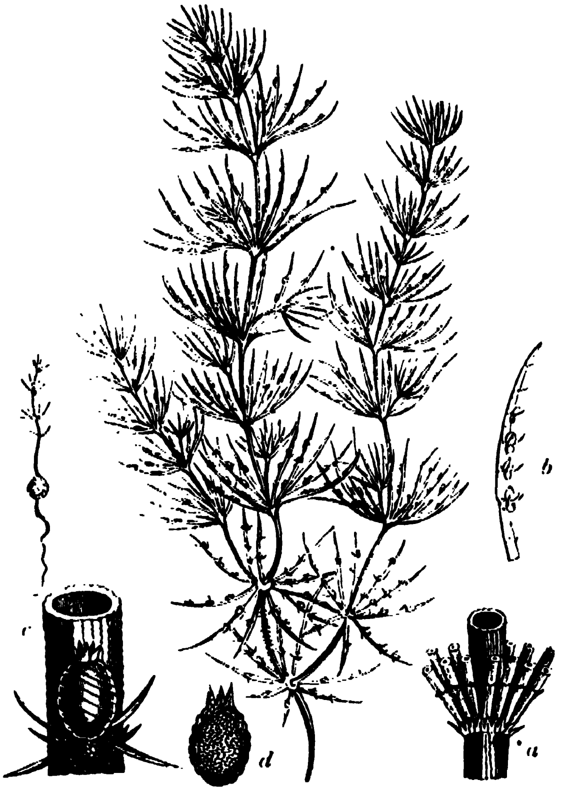
CHAMOMILE. [ANTHEMIS.]

CHAMP, a valuable kind of timber, produced in the East Indies by *Magnolia excelsa.*

CHANDELIER-TREE, a species of *Pandanus* which grows in Guinea and St. Thomas's, and which, on account of the arrangement of its dichotomous branches, has obtained this name. [PANDANUS.]

CHAODINEÆ, Chaotic Plants, a family invented by Bory, for the purpose of placing a number of the lower forms of plants or organic beings of uncertain character, which could not be placed amongst other well-defined groups of *Cryptogamia.* To this family were at one time assigned forms of *Diatomaceæ, Desmideæ, Nostoc,* and others.

CHARA'CEÆ, *Charas,* the Chara Tribe, a curious group of plants inhabiting pools and slow streams, to which they communicate a nauseous offensive odour, which is said to become a pestilential miasma, when, as in the Campagna of Rome, the plants are in great numbers. They are jointed leafless plants, with verticillate branches, composed either of one or of several tubes adhering in bundles, and either encrusted with calcareous matter (*Chara*), or transparent (*Nitella*). The reproductive organs are of two kinds. One named a nucule, is an oval sessile spirally striated body, with a five-cleft apex, and a number of grains in its interior; this has been looked upon as the pistil, and has been seen to grow into a young plant. The other, called the globule, is a reddish body consisting of triangular scales, inclosing a mass of elastic wavy threads, and has been named an anther.



Chara.

a, A portion of tubular stem, showing the bases of a whorl of leaves; *b*, leaf, bearing the organs of fructification; *c*, a single organ of fructification, greatly enlarged; *d*, upright section of the fruit; *e*, plant germinating.

The following is Schleiden's description of these organs:—"On the lateral branches, generally in the axis of the above-mentioned pair of cells, five cells may be seen spirally wound round a thick mass, and having their parallel extremities surrounded by a kind of pentagonal crown. From this thick granular mass a large cell (spore) is formed, filled with large granules of starch, mucus, and oil-globules, and with a substance that closely invests the spore-cells; and from being at first transparent subsequently becomes green or red, and finally black. The five investing cells then either become cartilaginous, and remain until the whole decays after germination, or they are converted into a gelatinous state, and then speedily dissolved after the sporocarp has fallen. Close below this sporocarp there may generally be seen, at the same time, seated upon a short cylindrical cell, another cell, which is at first simple and spherical, but from which eight [query always eight?] cells are gradually developed, which become flattened, and inclose a cavity that appears from its origin to be filled with a dense grumous mass. The eight cells expand into closely compressed radii, arranged side by side, increasing the circumference and depth of the whole body, whilst red granules are gradually deposited upon their inner wall. The dark contents are meanwhile developed into other cells, so that in the perfect organ a conical cell projects from the cell forming the pedicle into the cavity, and a cylindrical cell is formed from the middle of each of the eight cells of the wall. These new cells, which likewise contain pale-red granules, bear on their free extremity several spherical or truncated cylindrical cells, from which project many long filaments composed of minute cells. The spherical cells and the filaments form a dense coil in the centre of the cavity. In each separate cell of the filament we at first see a grumous mass, which however subsequently disappears, giving place to a spiral fibre coiled up in two or three turns, and which manifests a peculiar motion on escaping from its cell. These mysterious organs have, as yet, without any reason, been termed anthers."

There is however an analogy between these organs and the so-called spermatozoids of other *Cryptogamia*, that would lead to the inference that they perform the same functions. [Reproduction, Vegetable.] In addition to these organs, Montague has recently described bulbilli as present in the *Characeæ*, by which, he says, the species are frequently propagated.

The *Characeæ* are also highly interesting on account of the facility with which they exhibit the circulation of their fluids, and because of the light they thus appear to throw upon some of the more obscure of the phenomena of vegetable life. If one of the tubes of a *Chara* be observed under a pretty good microscope, by the aid of transmitted light, the fluid it contains will be distinctly seen to have a motion up one side of each tube, down the other, and then up again, after the manner of a jack-chain; and this goes on continually as long as the plant remains alive. No spectacle that we are acquainted with is more beautiful than this, if it is well seen with the aid of a good microscope. This movement was first described by Amici. It has led to the examination of other water plants; in most of which the same kind of circulation can be detected. The best account of these movements, with drawings, is that published by Varley in the 'Transactions of the Microscopical Society,' vol. ii. [Cyclosis.]

Remains of *Characeæ* are frequently found in the fresh-water Tertiary deposits, but not lower down. The species are met with almost everywhere in stagnant water in Europe, Asia, Africa, North and South America, and Australia. They are most prevalent in temperate climes. The species of *Chara* are of no known use. The stems of the species which are calcareous often present beautiful examples of crystals of carbonate of lime. They are easily cultivated in glass vessels, which is often done for the sake of examining their circulation under the microscope. In the *Chara* this can only be done after removing the calcareous incrustation, but in *Nitella* it is seen without any preparation. The family has three genera and thirty-five species. Their relations are evidently with the *Algæ* on the one hand, and the *Equisetaceæ* on the other.

CHARA'DRIADÆ, a family of Birds, placed by Mr. Vigors in the order *Grallatores*, or Waders. The genus *Charadrius*, including the True Plovers, the Dottrell, the Sea-Lark, the Sanderling, the Stone Curlew (*Œdicnemus*), the Long-Legged Plover (*Himantopus*), and the Spur-Winged Plover (*Charadrius spinosus*), was placed by Linnæus, in his 'Systema Naturæ,' between the genera *Tringa* and *Recurvirostra* [Avoset], in his order *Grallæ*.

Cuvier makes the family of Plovers (Les Pluviers, *Charadrius*, Linn.), comprising those genera which want the hind toe, and have a moderate bill compressed and convex at the end, consist of two genera, *Œdicnemus*, and the Plovers so called (*Charadrius*, Linn.), embracing the Golden Plover, *Charadrius Morinellus*, *C. Hiaticula*, &c. The Plovers are succeeded by the Vanneaux (*Vanellus*, Bechst., *Tringa*, Linn.), consisting of *Squatarola*, Cuv., and *Vanellus*, Cuv.; which are followed by *Hæmatopus* and *Cursorius;* after which last, judging from external form, he places the Çariama (*Microdactylus*, Geoff., *Dicholopus*, Ill.). [Çariama.]

The following is Mr. G. R. Gray's arrangement. He makes the *Charadriadæ* the first family of the *Grallatores*.

Sub-Family 1. *Œdicneminæ*.

Genera. *Œdicnemus*, Temm. (*Charadrius*, Linn.; *Otis*, Lath.; *Pluvialis*, Briss.).

Burhinus, Ill. (*Œdicnemus*, Shaw; *Charadrius*, Lath.).

Sub-Family 2. *Cursorinæ*.

Genera. *Cursorius*, Lath. (*Charadrius*, Gm.; *Tachydromus*, Ill.; *Orcophilus*, Gould).

Ortygodes, Vieill. (*Hemipodius*, Sw.; *Ortygis*, Steph.).

Pluvianus, Vieill. (*Charadrius*, Gm.; *Cursor*, Wagl.; *Hyas*, Gloger; *Ammoptila*, Sw.; *Cheilodromus*, Rüpp.).

Sub-Family 3. *Charadrianæ*.

Genera. *Glareola*, Briss. (*Hirundo*, Linn.; *Trachelia*, Scop.).

Squatarola, Cuv. (*Tringa*, Gm.; *Pluvialis*, Briss.; *Vanellus*, Bechst.; *Charadrius*, Pall.).

Vanellus, Briss. (*Tringa*, Linnæus; *Charadrius*, Wagler; *Gavia*, Klein).

Erythrogonys, Gould.

Philomachus, Mœhr. (*Parra*, Gmelin; *Vanellus*, Gmelin; *Hoplopterus*, Bonap.).

Charadrius, Linn. (*Pluvialis*, Ray).

Eudromias, Boie (*Charadrius*, Linn.; *Pluvialis*, Briss.; *Morinellus*, Gesn.).

Hiaticula, Mœhr. (*Charadrius*, Linn.; *Pluvialis*, Briss.; *Ægialites*, Boie).

Pipis, Licht. (*Charadrius*, Licht.).

Anarhynchus, Quoy and Gaim. (*Scolopax?* Raffles).

Sub-Family 4. *Hæmatopinæ*.

Genus. *Hæmatopus*, Linn. (*Ostralega*, Briss.; *Scolopax*, Scop.).

Sub-Family 5. *Dromadinæ*.

Genera. *Dromas*, Payk. (*Erodia*, Stanley; *Corrira*, Briss.?)

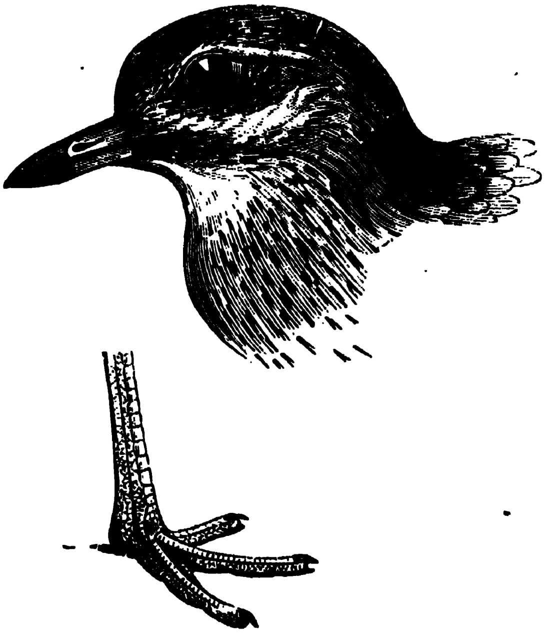
Esacus, Less. (*Carvanaca*, Hodgs.).

We now proceed to the consideration of some of the forms included in this family.

The first family of the order *Grallatores*, according to Mr. G. R. Gray's arrangement, is the *Charadriadæ*, which are divided by him into the following sub-families and genera:—

In illustration of this family we select principally the species inhabiting the British Islands.

Œdicnemus crepitans, the Great Plover. It is the *Otis Œdicnemus*, Pennant; *Charadrius Œdicnemus*, Montagu; *Oidicnemus Bellonii*, Fleming. It is also known by the common name of the Norfolk Plover. It is the Ostardeau of Belon; Le Grand Pluvier, ou Courlis de Terre, of the French; Gran Pivieri, Curlotte, Ciurlui, and Ciurlovi of the Italians; Lerchengraue Regenpfeifer, Grosser Brachvogel, and Grosse Bragvogel oder Gluth, of the Germans, among whom it is also called Triel, or Griel, according to Gesner, who thinks that it is the *Charadrius* of Aristotle; the Glin-braff of the ancient British. This genus connects the Bustards and Plovers.

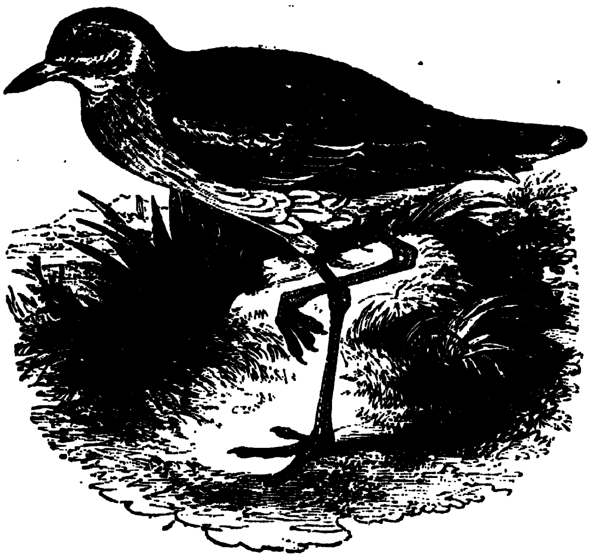


Head and foot of *Œdicnemus*.

Mr. Gould, who concurs in this view, observes that he has often had occasion to remark, that while the normal or typical groups are abundant in species, the aberrant forms, which appear to be created for the purpose of filling up the intervening chasms, are restricted for the most part to a limited number of species: thus while the Bustards and Plovers comprise a vast multitude of species, the genus *Œdicnemus* contains at most but five or six species, and these confined entirely to the regions of the Old World. ('Birds of Europe.')

The following is the character of the genus:—Bill strong, nearly straight, rather depressed towards the tip; culmen elevated, lower mandible angulated; nostrils longitudinal, pierced through and through the horny part of the middle of the bill, and most open anteriorly. Tarsi long; three toes, all before, united as far as the second joint by a membrane which skirts their edges. Wings moderate; first quill shorter than the second, which is longest.

The only British example of the genus is the Great Plover. It has all the upper parts of a reddish ashy-brown, with a longitudinal dash on the middle of each feather; space between the eye and the bill, throat, belly, and thighs, pure white; neck and breast slightly coloured with reddish and speckled with longitudinal brown streaks; a longitudinal white band on the wing; towards the middle of the first quill a great white dash, and a very small one on the interior barb of the second; lower tail-coverts ruddy; quill-feathers, except those of the middle, terminated with black; base of the bill bright-yellowish, the rest black; naked skin round the eyes, iris, and feet, pure yellow. Length from the bill to the feet 16 inches 2 lines. Male and Female.



Great Plover (*Œdicnemus crepitans*).

Such is Temminck's description of the adult bird; but the plumage varies in some individuals. For instance, in the specimen figured and described by Gould, in his 'Birds of Europe,' there is an obscure bar of white above and below the eye, and the ground-colour of the flanks and under surface is stated to be yellowish-white; whilst the yellow toes and feet are noticed as having a tinge of green.

The young birds have the colours less distinct, and are detected at the first glance by the highly dilated form of the upper part of the tarsus and by the size of the knee-joint. Temminck, who gives this description, adds that this form of the tarsus exists in the young of the year of all species of birds with long slender legs, but is particularly remarkable in the young *Œdicnemi.*

Rapid on foot, powerful in flight, which it executes in wide circles, and haunting downs and open places, this species is in general approached with difficulty by the sportsman, though it will often squat in places favourable to its colour, till it is almost trod on. Their shrill evening cry pierces the ear, and may be heard nearly a mile in a still night. Slugs, worms, reptiles, and, some say, mice are eaten by them; but the two former seem to be their favourite food. White, in a letter to Pennant, dated 30th March, 1768, says, "I wonder that the Stone Curlew (*Charadrius Œdicnemus*) should be mentioned by writers as a rare kind: it abounds in all the campaign parts of Hampshire and Sussex, and breeds, I think, all the summer, having young ones, I know, very late in the autumn. Already they begin clamouring in the evening. They cannot, I think, with any propriety be called, as they are by Mr. Ray, 'circa aquas versantes;' for with us, by day at least, they haunt only the most dry, open, upland fields, and sheep-walks, far removed from water: what they may do in the night I cannot say. Worms are their usual food, but they also eat toads and frogs." No nest receives the eggs, which are two or three in number, of a light brown or dirty white, with dusky blood-coloured blotches and streaks. "It lays," says the author of the 'History of Selborne,' "its eggs, usually two, never more than three, on the bare ground, without any nest, in the field; so that the countryman, in stirring his fallows, often destroys them. The young run immediately from the egg, like partridges, &c., and are withdrawn to some flinty field by the dam, where they sculk among the stones, which are their best security; for their feathers are so exactly of the colour of our gray-spotted flints, that the most exact observer, unless he catches the eye of the young bird, may be eluded. . . . *Œdicnemus* is a most apt and expressive name for them, since their legs seem swollen like those of a gouty man. After harvest I have shot them before the pointers in turnip-fields." In his Manuscript the same author remarks that they seem to descend in the night to streams and meadows, perhaps for water, which their upland haunts do not afford them.

Geographical Distribution.—Europe generally, where it seems to be migratory in many parts, in Britain and Germany for instance. Temminck notes it as abundant in the south of France (in which country Belon found young ones that could not fly at the end of October), Italy, Sardinia, the Greek Archipelago, and Turkey. It is also found in Asia and Africa. It occurred among the Trebizond collection of birds presented to the Zoological Society of London by Mr. Keith Abbott; and the localities attributed to it by Mr. Gould are Europe and Africa, but not India. ('Zool. Proc.,' 1834.) Col. Sykes however had previously recorded it among the birds of the Deccan: at least he says "there is no visible difference between the Dukhun and British species." ('Zool. Proc.,' 1832.) If it be the *Charadrius Kervari* of Hasselquist, which Linnæus and most authors suppose it to be, that traveller describes it as inhabiting Lower Egypt, near the sepulchres, and in the deserts. In Britain it arrives early in the spring. The following is the earliest period recorded by White:—"On the 27th of February, 1788, Stone Curlews were heard to pipe; and on March 1st, after it was dark, some were passing over the village, as might be perceived by their quick short note, which they use in their nocturnal excursions by way of watch-word, that they may not stray and lose their companions. Thus we see that retire whithersoever they may in the winter, they return again early in the spring, and are, as it now appears, the first summer birds that come back. Perhaps the mildness of the season may have quickened the emigration of the curlews this year." They are seldom seen after the beginning of October; but Markwick states that he received on the 31st January, 1792, a bird of this species which had been recently killed by a neighbouring farmer, who said that he had frequently seen it in his fields (Sussex) during the former part of the winter. This, perhaps, adds Markwick, was an occasional straggler, which, by some accident, was prevented from accompanying its companions in their migration. As the autumn advances, these birds collect into flocks, soon after which they leave this country. Norfolk, Suffolk, Kent, and Hampshire seem to be the favourite counties of the Stone Curlew; but it occurs, though rarely, in the Yorkshire Wolds, higher than which it does not seem to go in these islands. Mr. Selby says that he never met with it or heard of it in the more northern English counties, nor in Scotland. It does not occur in Mr. Thompson's Irish list in the 'Zoological Proceedings.'

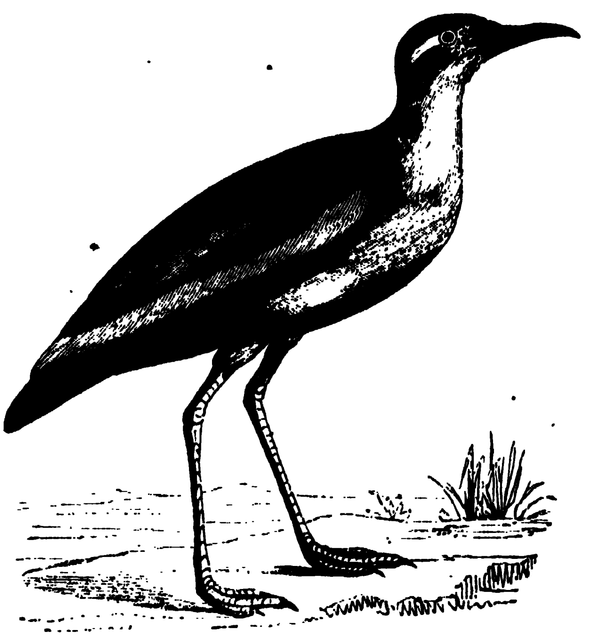
The Great Plover is a delicate bird for the table.

In the 'Portraits d'Oyseaux,' the following quatrain well describes the bird and the reason for the name given to it by Belon:—

> "L'on peut nommer cestuy-cy Ostardeau,
> Parcequ'il est approchant de l'Ostarde.
> Qui sous le ply des genoux l'os regarde,
> Le trouve gros plus qu' à nul autre oyseau."

Cursorius. Bill as long as head; mandibles arched, and compressed towards their extremities; base depressed; tip sharp and entire; nostrils basal, oval, with an oblong lateral opening. First quill longest. Legs long; three front toes separated throughout; middle toe much the longest, with a serrated claw.

C. Temminckii, Black-Bellied Courier, Swainson. The following is Mr. Swainson's specific character and description:—"Cream-coloured brown; top of the head and breast ferruginous, nuchal collar double; the lower, with the quills and middle of the body, black; the upper and the sides of the body white. Total length from the bill to the tail eight inches; bill one inch from the gape, and half from the end of the nostrils. Legs three inches from the naked thigh to the tip of the middle toe, the claw of which is serrated internally. Tail round; the middle feathers not spotted; the two next with a black dot near the tip, which, in the next pair, is further broken into two white dots; the outer pair white." ('Zool. Illust.,' pl. 106, first series). It inhabits Africa (Abyssinia.)



Black-Bellied Courier (*Cursorius Temminckii*).

C. Isabellinus, Meyer, Temminck; *C. Europæus*, 'Ind. Orn;' *C. Gallicus*, Gmelin; Le Courvite, Buff.; Cream-Coloured Plover, Latham; Cream-Coloured Courser, Pennant; Cream-Coloured Swift-Foot, Selby. It has been seen in France and England, but only as an occasional visitor. Thus we find (Mont. 'Orn. Dict.') that one was killed in France, where it was seen to run with great swiftness; another was shot near St. Alban's in East Kent, the seat of William Hammond, Esq., on the 10th of November, 1785, and he presented the prize to Dr. Latham. Mr. Hammond first met with it on some light land; and so little fearful was it, that having no gun with him at that time he sent for one, which did not readily go off, having been charged for some time, and, in consequence, he missed his aim; the report frightened the bird away, but after making a turn or two, it again settled within a hundred yards of him, when he was prepared with a second shot, which killed it. He observed it to run with incredible swiftness, considering its size, and at intervals to pick something from the ground: it was so bold as to render it difficult to make it rise in order to take a more secure aim on the wing. The note was unlike that of any known bird. Colonel Montagu says that one was shot in North Wales in the year 1793, and preserved in the collection of the late Professor Sibthorp at Oxford. Mr. Atkinson, author of 'The Compendium of Ornithology,' was also in possession of a specimen shot at Netherby, in April, 1816.

Another of these birds was taken in Austria; and the young bird in the Darmstadt Museum, alluded to by Temminck, was probably killed in Europe. Mr. Fox ('Zool. Journal,' vol. iii., p. 492) records the death of one shot on the 15th October, 1827, under Timberwood Hill, in Charnwood Forest, Leicestershire, by a tenant of Mr. T. Gisborne. He described it as coming flying over his head, uttering a cry with which he was unacquainted, and it settled near him. Some idea of the enormous prices which were at one time given by collectors for rare birds killed in Britain may be formed from the sum which Dr. Latham's specimen produced: Mr. Fox says it was purchased for 83 guineas.

Glareola, Brisson. Bill short, hard, convex, curved for upwards of half its length, and compressed towards the point. Nostrils at the sides of the base, oblong, and obliquely cleft. Legs feathered nearly to the knee; toes, three before and one behind, the outer united to the middle one by a short membrane; claws long, and drawn to a fine point. Wings very large, the first quill-feather the longest. Tail more or less forked. (Gould.)

Example, *G. Pratincola* (*Hirundo Pratincola*, Linnæus), the Collared Pranticole. Both male and female when old have the summit of the head, nape, back, scapulars, and coverts of the wings gray-brown; throat and front of the neck white slightly tinged with red, which colour is encircled or framed, as it were, by a very narrow black band, which ascends towards the corners of the bill; space between the eye and the bill black; breast whitish-brown; under coverts of the wings chestnut-red; lower parts white, clouded with reddish; coverts of the tail and origin of the caudal feathers pure white, the rest blackish towards their end; bill black, red at its base, iris reddish-brown; naked circle round the eyes bright-red; feet reddish-ash. Tail very much forked. Length rather more than 9 inches. (Temm.)

In this state it is the Perdrix de Mer of Brisson, &c.; the Perdrix de Mer Ordinaire et à Collier of Gerard; Austrian Pratincole of Latham; Das Rothfüssige Sandhuhn of Bechstein; Das Oestrichische Halsband, and Südliche Sandhuhn, of Brehm; and Pernice di Mare of Savi.

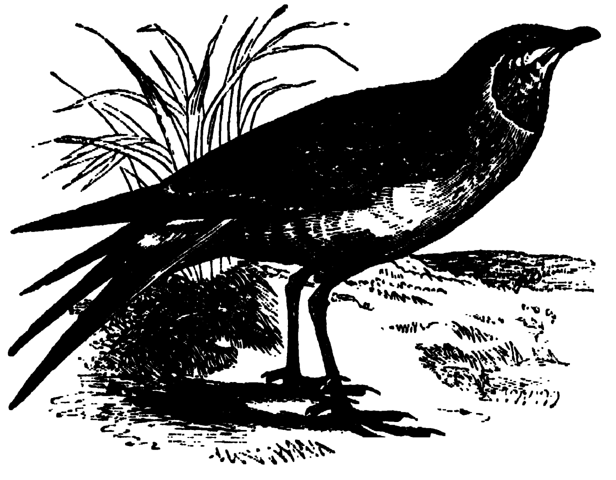
Varieties.—The gray-brown brighter or deeper: the white of the throat more or less clouded with reddish or bright russet; the gular black band more or less intense in colour, and often accompanied by a very small white line. The band too is often only indicated by small black spots. (Temm.)

When young the upper parts are brown-ash, clouded with deeper undulations and whitish borders; throat tarnished white, surrounded with brown spots disposed so as to replace the band which surrounds this part in the old birds; breast and belly deep gray with brown spots, but sometimes without spots; the tail less forked, and the lateral feather much shorter than in the old.

In this state it appears to be La Perdrix de Mer à Collier, la grise, la brune, et la Giarole of Sonnini, of Buffon; La Perdrix de Mer des Maldives, de Coromandel, et de Madras, of Sonnerat; Das Braunringige Sandhuhn, and Gefleckte Sandhuhn, of Bechstein; and Collared and further varieties of Pratincole of Latham.

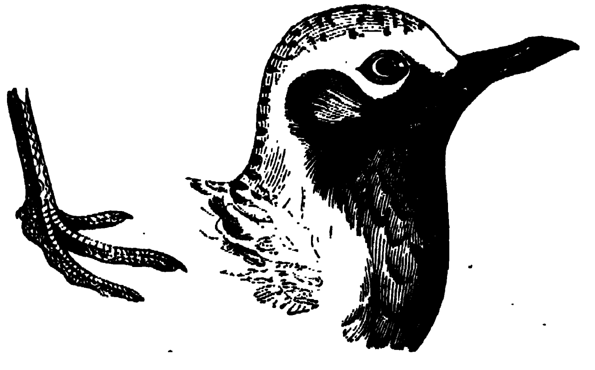
"The genus *Glareola*," says Mr. Gould in his great work on the 'Birds of Europe,' "appears to be strictly confined to the Old World, no transatlantic example having ever been discovered, nor indeed are we aware of any form in the ornithology of America which at all approaches the present. Three species are all that are as yet discovered. Of these, two (the *G. grallaria* and the *G. lactea*) are peculiar to the eastern provinces of Asia and Africa; the other, the bird now before us (*G. torquata*), is spread throughout the warm and temperate regions not only of these continents, but Europe also: hence it would seem as if nature endeavoured to make up by extent of habitat for the limitation of species. Still however, although thus diffused, the Prantincole may be said to be truly a native of the eastern provinces of Europe on the Asiatic borders, and especially Hungary, where wide tracts of morass and flat lands, abounding in lakes both fresh and saline, and traversed by mighty rivers, afford it food and security. 'In Hungary,' says M. Temminck, 'among the immense morasses of the lakes Neusidel and Balaton, I have been in the midst of many hundreds of these birds;' and we might add that it is no less abundant in Western Tartary. In England it is only an occasional visitor; but in Germany, France, and Italy, it is a bird of periodical occurrence."

M. Temminck, in the last part of his 'Manuel,' states that it breeds in Sardinia, and that it is very abundant in Dalmatia, on the borders of the lake Boccagnaro, on its spring passage. The eggs he describes as being yellowish-white. "With the long wings and forked tail of the swallow"—we again quote Mr. Gould—"the Pranticole possesses that rapidity and power of flight for which the bird is so remarkable. It takes its food, which consists of insects, and especially such as frequent marshes and the borders of rivers, while on the wing, darting along in the chase with the rapidity of an arrow; nor is it less distinguishable for celerity on the ground, and often catches its prey as it nimbly runs along. This elegant and graceful bird incubates in the concealment afforded by reeds, osiers, and tall herbage, laying three or four white eggs." A pair of Pratincoles were shot at Yarmouth in 1827; another in Wilbrahan Fen in Cambridgeshire in 1835; and a specimen at Blakeney in Norfolk, in May, 1845.



Collared Pratincole (*Glareola Pratincola*).

Squatarola, Cuvier. Bill rather strong, cylindrical, straight, nearly as long as the head; the tip or horny part about half the length of the whole bill, tumid and arched, with the tomia bending inwards; nasal grooves wide, half the length of the bill; mesorhinium depressed below the level of the tip; nostrils longitudinally pierced in the membrane of the groove, linear, oblong. Wings rather long, acuminate, with the first quill-feather the longest. Legs slender, of mean length, naked above the tarsal joint; feet four-toed, three before and one behind; front toes joined at their base by a membrane, that portion of it between the outer and middle toe being the longest; hind toe very small or rudimental; tarsi reticulated. Plumage thick, close, and adpressed. (Gould.)



Head and Foot of *Squatarola*.

S. cinerea (*Tringa Squatarola*, Linn.), the Bastard or Gray Plover.

Adult Male and Female, Winter Plumage.—Front, throat, middle of the belly, thigh, abdomen, and upper coverts of the tail, pure white; space above the eye, front of the neck, sides of the breast and sides, white, varied with brown and ashy spots; upper parts blackish-brown, variegated with greenish-yellow spots, but the whole of the feathers terminated with ash-colour and whitish; long internal feathers of the wings deep black; lower coverts of the tail marked on their external barbs with small diagonal brown bands; tail white, but reddish towards the end, striped with brown bands, which are pale and few, and placed on the lateral feathers; bill black; iris blackish; feet ashy-black. Length rather more than 10 inches.

Adult Male and Female, in their Spring or Nuptial Plumage.—Space between the eye and the bill, throat, sides and front of the neck, middle of the breast, belly, and sides, deep black; front, a large band above the eyes, lateral parts of the neck, side of the breast, thighs, and abdomen, pure white; nape variegated with brown, black, and white; occiput, back, scapulars, and coverts of the wings, deep black; all the feathers of these parts terminated by a large space of pure white; large white spots on the greatest of the wing-coverts and on the scapulars; oblique black bands on the lower tail-coverts; feathers of the middle of the tail striped with white and black.

The young before the moult resemble more or less the adult birds and the young in winter; the front, space above the eye, sides of the neck, and sides are variegated with larger but paler spots; upper parts of a bright-gray tint varied with whitish, also a little whitish at the extremity of the quills; transverse bands of the tail gray. (Temm.)

In the first of these states of plumage the bird is the *Tringa Squatarola*, Gmel.; Le Vanneau Varié, Buff.; and Gray Sandpiper, Lath. ('Syn.')

In the second it is the *Vanellus melanogaster*, Bech.; *Tringa Helvetica*, Gmel.: *Charadrius apricarius*, Wils.; Le Vanneau Suisse, Buff.; Swiss Sandpiper, Lath.; and Schwarzbauchiger Kiebiz, Meyer.

The young before the moult are *Tringa Squatarola, var.*, Gmel.; Le Vanneau Pluvier, and Vanneau Gris, Buff.; Gray Sandpiper, Lath.; and Schwarzbauchiger Kiebiz im Herbstkleide, Meyer.

M. Temminck, who gives these synonyms, remarks in his 'Manuel,' that at the two epochs of the moult, individuals are found which have the deep black of the lower parts sprinkled with some white feathers, or when the white predominates it is variegated with some black feathers. The birds in winter plumage and the young may, he observes, be easily distinguished from those of the Golden Plover, first by the presence of the posterior toe, and secondly by the long black feathers which are found inside of the wings, near the body; the rest of the plumage differs so little at these epochs, that one might be easily mistaken.

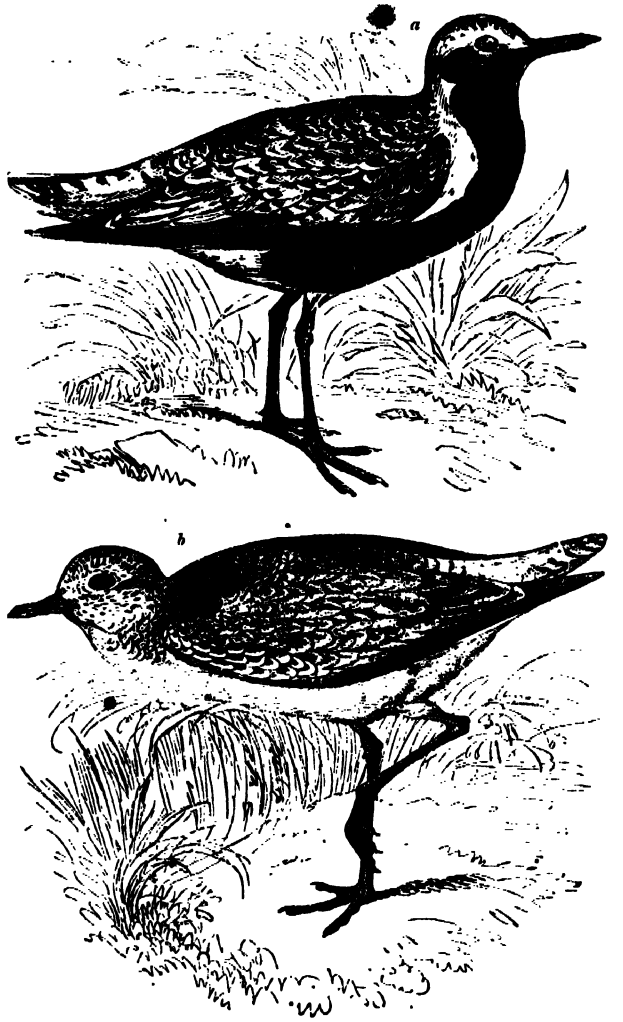
This species is the *Charadrius hypomelas* of Wagler, and the Gray Squatarole of Shaw. It appears to be the Pluvier Gris of Belon, and in the 'Portraits d'Oyseaux,' &c., is the following loyal quatrain under the figure of the bird:—

> "De nuict seulet, de jour en compagnie,
> Va le Pluvier suyvant son appelleur.
> Par la voit-on, que c'est bien le meilleur,
> Qu'une gent soit par un roy gouvernée."

M. Temminck, who, in the fourth part of his 'Manuel' (1840), protests against the generic separation of this form, not without a passing but sweeping censure on "toutes les autres coupes nouvelles," adds to the synonyms *Squatarola varia et Helvetica*, Brehm.; Kiebiz Regenpfeifer, Naum; Pivieressa, Savi; and Sprackling Vipa, Nils.

In Britain, where this bird is not numerous, and principally known as a migratory species, it is found on the coast "in oozy bays, or at the mouths of rivers," where it feeds upon worms, marine crustaceans, &c. The bird runs well, and its whistle is like that of the Golden Plover, but not so shrill. If killed in good season it is delicious for the table. The nest is of the most rude construction. A shallow depression in the earth is lined with a few pieces of dried bents or straw, and there four eggs generally, which are oil-green blotched with black, are deposited. According to Wilson and Nuttall, this Plover has often in the temperate parts of the United States two broods in a season, though it has only one in Massachusetts, where their nests are of rare occurrence. During the summer both young and old feed much upon various kinds of berries, particularly those of the early bramble, called dew-berries, and their flesh is then highly esteemed. About the last week in August they repair with their young to the borders of the sea-coast, where they assemble in great numbers, feeding on small shell-fish, shrimps, and other small marine animals. Grasshoppers and other insects that abound in the fields are also eaten by them. "They are," says Nuttall, "extremely shy and watchful, uttering a loud rather plaintive whistling note as they fly high and circling in the air, and are so often noisy, particularly in the breeding season, as to have acquired among many of the gunners along the coast the name of the Black-Bellied Killdeer. They usually linger round the sea-coast in the Middle States till the commencement of November, when the frosts beginning sensibly to diminish their prospect of subsistence, they instinctively move off towards the south, proceeding probably at this time under the shade of twilight, as moving flocks are nowhere, as far as I can learn, seen by day. About the middle of September, in the marshes of Chelsea (Mass.) contiguous to the beach, they sometimes assemble at daybreak in flocks of more than a thousand individuals together, and soon after disperse themselves in companies on the shores, to feed upon the small shell-fish and marine insects (*Crustacea*). This crowding instinct takes place a short time previous to their general migration southward." ('Manual of the Ornithology of the United States and Canada.')

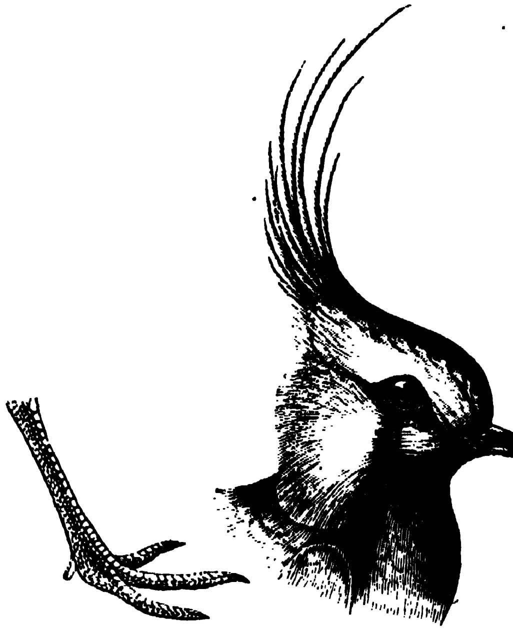
The Gray Plover is found in all the temperate countries of Europe. More abundant in France than in Germany; rare in Switzerland; common enough in the islands and on the coasts of Holland. Abundant in summer in the regions of the Arctic Circle and of Oriental climates, where it breeds. M. Cantraine killed a young one in the Strait of Boniface. (Temm.) Dr. Von Siebold and M. Bürger saw it in Japan, and M. Temminck states that he has seen individuals from that locality in both summer and winter plumage. Sir John Richardson, who notices it as the Toolee-areeoo, or Tooglee-aiah, of the Esquimaux, says that it is observed in the Fur Countries in similar places to those frequented by the Golden Plover, though it is not equally common, and that it breeds in open grounds from Pennsylvania to the northern extremity of the continent. He describes a specimen killed at Hudson's Bay (lat. 57°) in August 1822. Captain James Ross, in the Appendix to Sir John Ross's 'Last Voyage,' observes that it was more rarely met with than the Golden Plover, but was found breeding near the margins of the marshes immediately to the south-west of Fury Point in considerable numbers. Some specimens were also obtained near Felix Harbour. It is met with in Egypt, and upon the confines of Asia, in Siberia, &c. (Selby.) The last-quoted author states that in Britain there are a few stations on the coast of Northumberland where it is found during the whole winter, but only in families or small flocks. It generally arrives about the middle of September, sometimes even earlier, he adds, at which time several of the old birds still retain a part of their summer plumage. In the month of May they go northward. Mr. Gould says that they appear in the greatest abundance in this country while performing their periodical migrations in the months of April and May along the coasts of Lincolnshire, Norfolk, Suffolk, Essex, and Kent. ('Birds of Europe.')



Gray Plover or Gray Lapwing (*Squatarola cinerea*).
a, Spring plumage; *b*, Winter plumage.

Vanellus (Briss.). Bill shorter than the head, straight, slightly compressed, the points of both mandibles horny and hard. Nasal groove wide, and reaching as far as the horny tip. Nostrils basal, linear, pierced in the membrane of the nasal groove. Legs slender, with the lower part of the tibiæ naked. Feet 4-toed, three before and one behind, united at the base by a membrane; hind toe very short, articulated upon the tarsus. Tarsi reticulated. Wings ample, tuberculated, or spurred. The first three quill-feathers notched or suddenly narrowed towards their tips, and shorter than the fourth and fifth, which are the longest. (Gould.)

V. cristatus (*Tringa Vanellus*, Linn.), the Peewit, or Lapwing. The male in winter plumage has the occipital feathers very long, loose barbed, and curved upwards. Top of the head, crest, front of the neck and breast, glossy black; upper parts deep green with brilliant reflections; sides of the neck, belly, abdomen, and base of the tail, pure white; tail-feathers terminated by a large black space, with the exception of the external feather; lower coverts ruddy, bill blackish; feet red-brown. Length rather more than 12 inches. The female has the black of the throat and breast less deep. The young before the moult have the occipital crest shorter; some blackish colour below the eyes; the throat varied with black and ashy brown; all the feathers of the upper and lower parts terminated with ochreous yellow; feet ashy-olive. The spring or nuptial plumage is scarcely distinguishable by the greater brilliancy of the reflections on the back and wings, and by the deeper intensity of the black of the throat and breast. The crest however is longer, and the colour of the feet bright reddish.



Head and foot of Peewit, or Lapwing (*Vanellus cristatus*).

Accidental Varieties.—Pure white. Yellowish white with faint indications of the deeper colours. One or other part of the body speckled with white feathers. (Temm.)

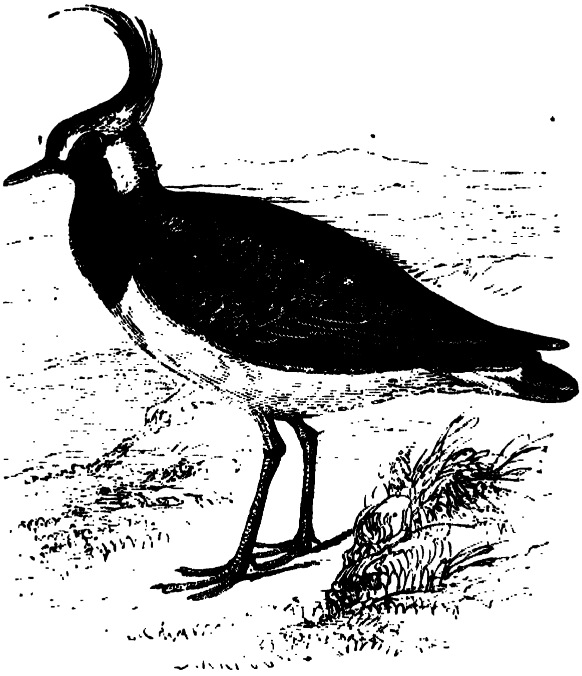
This species is Le Vanneau of the French; Paoncella Commune of the Italians; Gehaübte Kiebiz of the Germans; De Kievit of the Netherlanders; Peaseweep, Peewit, Bastard Plover, Lapwing, and Wype, of the British; Cornchwigel of the Welsh. It is also the Wipa, Kowipa, and Blæcka, of the Swedes; Vibe and Kivit of the Danes; and, according to Belon, Αἶξ of the Greeks (Aristot., 'Hist. Anim.,' viii. 3); Pavonzino and Parruchello of the Italians; and in some provinces Dixhuit and Papechieu of the French.

The habits of this species very much resemble those of the other Plovers, and the arts by which the parents try to lead either dog or man from their eggs or young by counterfeiting the gait of a wounded bird, &c., are as well if not better known as the stratagems of its congeners on the like occasions. This is the bird which furnishes the plover's eggs of the London market; and those who rob the nest are, it is said, careful not to take all, but they leave one or two, so as to induce the bird to go on laying, which she generally does to make up her number. The full compliment, when the bird is not robbed, is generally four, and they are olive-coloured, spotted and blotched with black. That part of the egg which is usually called the white (the albumen) is transparent when boiled, and has somewhat of a bluish tinge. The nest, if nest it may be called, is the bare earth. It haunts the borders of rivers, lakes, plains, and marshy places, and is generally to be found near the sea-shore in the winter. This part of its habits well agrees with those described as proper to Aristotle's *Aἶξ*, according to the reading given by Belon. This elegant bird seems to have been as much esteemed by the French for the table as by our own countrymen. In the 'Portraits des Oyseaux' the following quatrain appears under the figure of the bird:—

> "Voy cy dessus le portraict du Vaneau,
> Et le voyant, pourras tu veue paistre;
> Mais si tu veulx d'un bon morceau repaistre
> Il y a peu de meilleurs oyseaux d'eau."

In the 'Northumberland Household-Book,' 'Wypes' are charged at one penny each, and they are among the birds admitted to his lordship's own 'mees.'

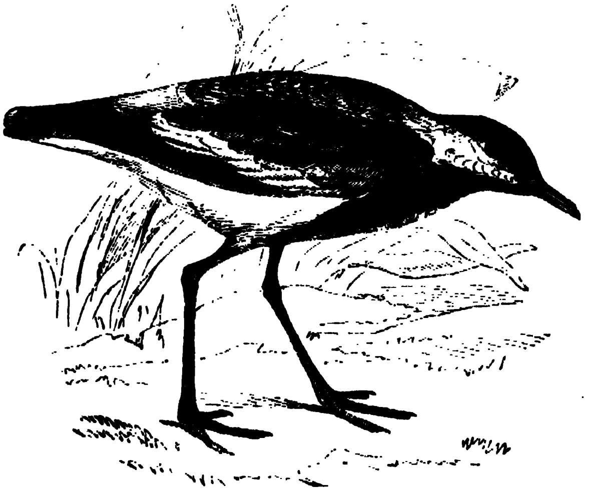
The Peewit is spread over the whole of Europe, and is particularly plentiful in Holland. Mr. Gould states that he has seen specimens in collections from India and Africa. It is noted by Messrs. Dixon and Ross as occurring in great numbers near Erzeroom, arriving at the end of March, and departing at the end of November. During the summer it frequents the river (Kara-Su, or northern branch of the Euphrates), but on its arrival, and previous to its departure, it is found in moist fields. The native name is Kiz-Cooshóo (Maiden's Bird), or Kahmaum Cooshóo (Bath-Bird). *Vanellus Keptuschka*, and *Charadrius Morinellus* and *C. minor* were found by those gentlemen at the same locality. ('Zool. Proc.,' 1839.) It appears in the 'List of Birds' seen in Japan, by Dr. Von Siebold and M. Bürger; and Temminck states that individuals from that locality differ in nothing from those of Europe.



Peewit, or Lapwing (*Vanellus cristatus*).

This species is confined to the Old World; but Captain P. P. King, R.N., has described a second species from the Straits of Magalhaens. It is figured in the 'Illustrations of Ornithology,' under the name of *Squatarola cincta*.

Philomachus, the Spur-Winged Plover. It is the *Philomachus spinosus* (*Charadrius spinosus*, Linn.; *Pluvialis Senegalensis armata*, Briss.; *Pluvianus spinosus*, Gould.)



Spur-Winged Plover (*Philomachus spinosus*).

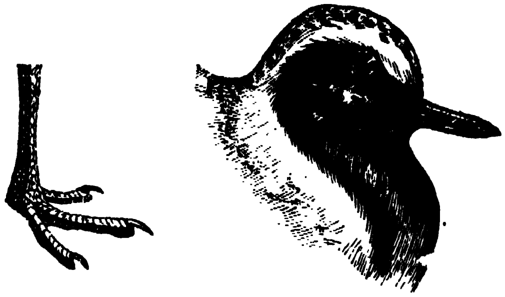
When the male and female are in perfect plumage all the summit of the head and occiput, throat, front of the neck, breast, sides, quills, and three-fourths of the tail are black; region below the eyes, lateral base of the bill, sides of the neck, nape, long feathers on the sides, inside of the wings, the whole border of the wing, thighs, abdomen, rump, and first fourth of the origin of the tail, pure white; the whole of the mantle, quills nearest the body, as well as all the coverts, gray-brown, more or less deep or umber-colour; two lateral feathers of the tail terminated with white. Length 10 to 11 inches.

This is Le Pluvier à Aigrette, Le Pluvier Huppé de Perse, and the Pluvier Armé du Senegal, of Buffon; Spur-Winged and Black-Breasted Indian Plover of Latham.

Little or nothing is known of the habits of this species, with the exception of what we learn from Dr. Latham, who says that it inhabits Russia, and is frequent near Aleppo, about the river Coie. "The Spur-Winged Plovers," says he, "are very numerous and exceedingly noisy, have a hasty and continual movement of the head and neck, drawing them up briskly, and then stretching them quickly forward, almost as if they were making hasty and eager bows."

M. Temminck gives Egypt and Senegal as the habitat of this bird, and says that it shows itself accidentally in Italy, but is said to be more common in the islands of the Grecian Archipelago. In Greece, he adds, great numbers are found; and Professor Nordmann killed one in Russia.

Charadrius (Linn.). Bill slender, straight, compressed, shorter than the head; nasal furrow prolonged more than two-thirds; mandibles enlarged towards the tip. Nostrils basal, jagged, cleft longitudinally in the middle of a large membrane which covers the nasal fossa. Toes three, directed forwards, the external united to the middle one by a short membrane; the inner toe free. Tail square or slightly rounded. Wings moderate, first quill-feather longest. (Gould.)



Head and foot of Golden Plover (*Charadrius pluvialis*).

C. pluvialis (Linn.), the Golden Plover. The old male in winter plumage has the top of the head, as well as all the upper parts of the body, wings, and tail, sooty black, marked with large spots of golden yellow, disposed on the borders of the barbs of the feathers; sides of the head, neck, and breast varied with ashy brown and yellowish spots; throat and lower parts white; quills black, shafts white towards the end; bill blackish; feet deep ash-colour; iris brown. Length rather more than 10 inches.

The young of the year have the upper parts ashy black with spots of yellowish ash. (Temm.)

In this garb the birds are, according to Temminck, *C. pluvialis*, Gmel.; *C. auratus*, Suckow; Le Pluvier Doré, Buff.; Golden or Green Plover, Lath; Goldregenpfeifer, Bechst.; Piviere Dorato, of the 'Stor. degl. Ucc.'; Goud Plevier, Sepp.

The old male and female in summer or nuptial plumage have the upper parts deep black; over all the borders of the feathers are disposed small spots of a very bright golden yellow; front and space above the eyes pure white; lateral parts of the neck white also, but varied with great black and yellow spots; throat, front of the neck, and all the other lower parts, deep black.

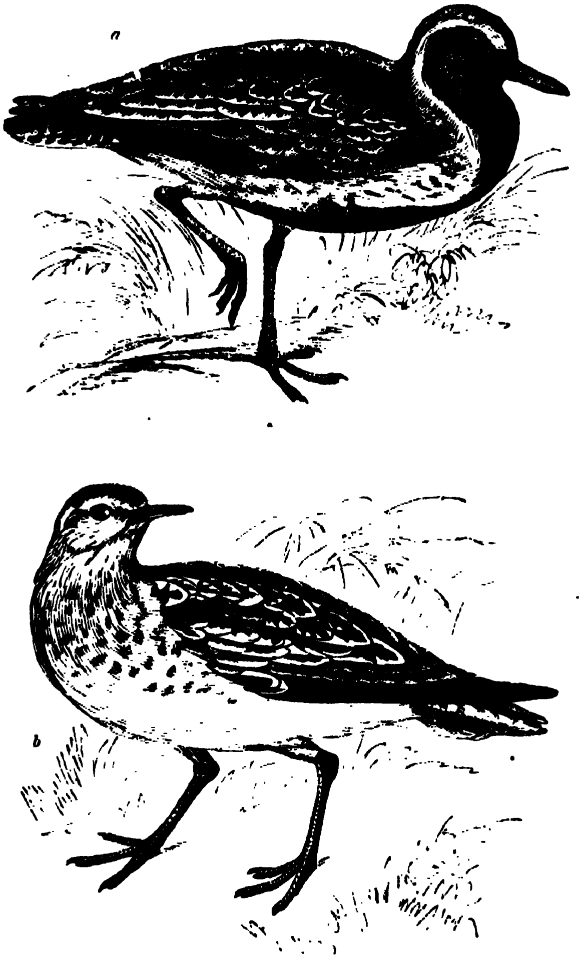
White and black mingled are often seen on the lower parts of the feathers during the moult. This livery is always to be seen on the young birds, even after their first spring moult. (Temm.)

In this state the bird is, according to M. Temminck, *C. apricarius*, Gmel.; Le Pluvier Doré à Gorge Noire, Buff.; Alwargrim Plover, Lath.

In the fourth part of his 'Manuel,' M. Temminck adds the following synonyms:—*C. auratus*, Naum.; Der Platköpfige, Hochsternige, Mittlere, und Hochköpfige Goldregenpfeifer, Brehm.; Brockfogel, Nils.; and Ploiere, Savi.

This species is also Le Pluvier Guillemot of Belon (who says that it is named Pluvier, "pour ce qu'on le prend mieux en temps pluvieux qu'en nulle autre saison," and he gives an amusing account of the mode of taking these birds by the peasants); Der Rechte Brachvogel of the Germans; Hawk's Eyes of the Hudson's Bay residents (?); Cwttyn yr aur of the ancient British.

Mr. Selby gives a most correct and interesting account of the habits of the bird in this country:—"About the end of May or beginning of June the females begin to lay, making but a little artificial nest, a small depression in the ground amidst the heath being generally taken advantage of, and lined with a few dry fibres and stems of grass. The eggs are four in number, rather larger than those of the lapwing, of a cream-yellow inclining to oil-green, with large irregular confluent blotches or spots of deep umber-brown. The young, when excluded, are covered with a beautiful particoloured down of bright king's yellow and brown. They quit the nest as soon as hatched, and follow their parents till able to fly and support themselves, which is in the course of a month or five weeks. The old birds display great anxiety in protecting their young brood, using various stratagems to divert the attention of an enemy; among others, that of tumbling over, as if unable to fly, or feigning lameness, is most frequent, and appears indeed to be the instinctive resort of those birds that construct the nest and rear their young on the ground. When aware of an intruder near, the female invariably runs to some distance from her nest before she takes wing, a manœuvre tending to conceal its true situation; and the discovery of it is rendered still more difficult by the colour and markings of the eggs assimilating so closely to that of the ground and surrounding herbage. The usual call-note of the Plover is a plaintive monotonous whistle, by imitating which it may frequently be enticed within a very short distance. In the breeding season a more varied call is used, during which it flies at a great elevation, and continues soaring round for a considerable time. Towards the end of August these birds begin to leave the moors (having there congregated in large flocks), and descend to the fallows and the newly-sown wheat-fields, where an abundance of their favourite food can be readily obtained. At this season they soon become very fat, and are excellent at the table, their flesh not being inferior in flavour to that of the Woodcock or any of our most esteemed sorts of game. In these haunts they continue till severe weather approaches, when they either move nearer to the coast or migrate to the southern parts of the kingdom. They fly with strength and swiftness, and if disturbed, when in large flocks, generally perform many aërial evolutions and rapid wheelings before they again settle on the ground. The Golden Plover is a nocturnal feeder, and during the day is commonly seen squatted upon the ground or standing asleep, with the head drawn down between the shoulders. Its food consists of earth-worms, slugs, insects, and their larvæ, particularly those of the Lepidopterous tribe, many rare species of which I have, upon dissection, found in their stomachs and gullet during the summer season. It runs very fast, and, when wounded, is difficult to be caught without the aid of a dog."



Golden Plover (*Charadrius pluvialis.*)
a, Summer dress; *b*, Winter dress.

This species has been always considered, and most justly, a delicious dish. It figures in the old bills of fare accordingly. Thus in the account of Sir John Nevile, of Chete Knight, of the viands, &c., used at the marriage of his son-in-law Roger Rockley and his daughter Elizabeth Nevile, the 14th of January, in the seventeenth year "of the reigne of our soveraigne lord king Henry VIII," we find in the second course, "Item, plover, 8 of a dish," and among the charges, "Item, in plover, 3 doz., 5*s*." In the charge of the said Sir John Nevile, at Lammas Assizes, twentieth of Henry VIII., we also find "Item, 6 doz. plovers, 12*s*." Four hundred plovers appear among "the goodly provision" at the intronization of George Nevell, archbishop of York, in the reign of Edward IV. Drayton, in his 'Polyalbion,' makes Lyndsey boast that her "fowle more ayrie are" than those of Holland (Lincolnshire);

> "And make fine spirits and blood;
> For neere this batning isle, in me is to be seene,
> More than on any earth, the plover grey and greene."

There is evidence of the presence of the Golden Plover in each of the four quarters of the globe. Mr. Gould indeed, in his observations on the geographical distribution of the species collected by Mr. Keith Abbot in the neighbourhood of Trebizond, notices the bird as inhabiting Europe, and the adjoining portions of Africa and Asia, but not America. ('Zool. Proc.,' 1834.) Now Temminck expressly says that the species is the same in America and Asia. Sabine also (Parry's 'First Voyage') makes Wilson's *C. apricarius* and the Golden Plover identical, and states that it breeds in the swampy parts of the North Georgian Islands in considerable abundance. Richardson states that the breeding-quarters of this well-known bird are the Barren Grounds and the coasts and islands of the Arctic Sea. "It hatches," he says, "early in June, and retires southward in August. Numbers linger on the muddy shores of Hudson's Bay and on the sandy beaches of rivers and lakes in the interior until the hard frosts of September and October drive them away. At this period they are very fat, and are highly prized by the epicures of the Fur Countries. They make but a short stay in Pennsylvania, and are said to winter beyond the United States." ('Fauna Boreali-Americana.')

Captain Sir James Ross, R.N., notices it as abundant during the breeding season in most parts of the arctic regions, and he found them plentifully in the neighbourhood of Felix Harbour, feeding in the marshes in company with *C. semipalmatus* (American Ring-Plover). (Sir John Ross's 'Second Voyage.') Nuttall remarks that the bird is, according to the season of the year, met with in almost every part of the world, particularly in Asia and Europe, from Kamtchatka to China, as well as in the South Sea Islands, and from Arctic America, where it breeds, to the Falkland Islands. The Prince of Canino ('Birds of Europe and North America') appears, on the other hand, to agree with Mr. Gould, for the Prince makes the American analogue of *C. pluvialis*, Linn., *C. Virginiacus*, Borkh. (*C. pluvialis*, Wils.); and Colonel Sykes notes it among the birds of the Deccan, and as identical with Javanese specimens, smaller indeed than one North American specimen and two English specimens in the British Museum, but absolutely identical with other British specimens. He says that it is rare in the Deccan, and appears only in the cold weather. In the stomach he found beetles, land-insects, and coarse sand. ('Zool. Proc.,' 1832.) It appears among the list of birds seen in Japan by Dr. Von Siebold and M. Bürger; and Temminck states that those killed there did not differ essentially from those of Europe. Mr. Selby allows a wide geographical range to it, though not to the extent supposed by many naturalists, the birds which have been considered by them as belonging to this species being of a different one, namely, *C. marmoratus* of Wagler. Instead therefore of extending the range of the Golden Plover to America, Australia, and other parts of the southern hemisphere, he feels inclined to limit it to Europe, Northern Asia, and some few districts in the north of Africa. ('British Ornithology.')

C. Morinellus, Linn., the Dotterel. It is *Eudromias Morinella*, Boie; *E. Morinella montana et stolida*, Brehm, according to Temminck.

This bird in its winter plumage has the top of the head and occiput blackish-ash; large eyebrows of reddish-white uniting on the occiput; face white, dotted with black; upper parts blackish-ash tinged with greenish, all the feathers of those parts framed as it were with ruddy colour; breast and sides reddish-ash; the large patch on the breast and the middle of the belly pure white; shaft of the first quill white, except towards the end, tail terminated with white; bill black; iris brown; feet greenish-ash. Length more than 8 inches.

The young have the tints more ashy; top of the head reddish or rusty, varied with longitudinal spots; the ruddy colour which frames as it were the feathers of the upper parts less vivid; tail terminated with bright ruddy.

In their summer or nuptial plumage the very old male has the face and eyebrows very pure white; summit of the head and occiput blackish; nape and sides of the neck ashy; feathers of the mantle and wings bordered with very deep ruddy; on the breast a narrow brown band, succeeded by a large white cincture; part below the breast and sides very bright ruddy; middle of the belly deep black; abdomen reddish-white. The female is of a ruddy colour on the sides often clouded with ash-colour; black spot of the middle of the belly less apparent than in the male, or varied with white feathers.

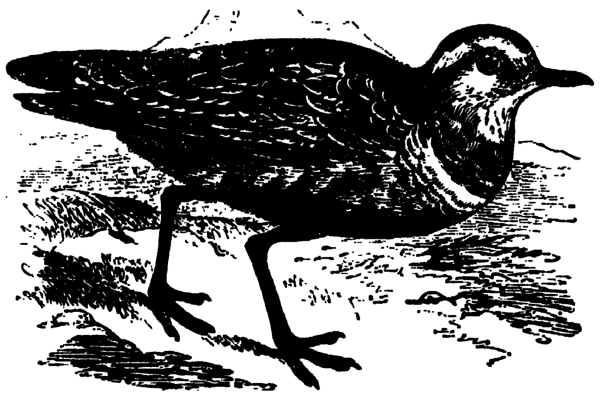
This is the Pluvier Guignard and Pluvier Solitaire of the French; Piviere de Corrione and Piviere Tortolino of the Italians; Der Dumme Regenpfeifer of the Germans; Dotterel, Dotterell, and Dottrell of the British, and Hullan of the Welsh.

Drayton sings, of this bird—

> "The Dotterell, which we think a very dainty dish,
> Whose taking makes such sport as man no more can wish;
> For as you creepe, or cowre, or lye, or stoupe, or goe,
> So marking you (with care) the apish bird doth doe,
> And acting everything, doth never mark the net,
> Till he be in the snare which men for him have set."

Poets have a right to a little licence, and in many of the older prose writers a similar account of the silly mimicry of the bird is given. "The Dotterel," says Mr. Selby, "has always been considered a stupid bird, but for what reason I cannot conceive. I allow that, on its first arrival, it shows but little fear of man, but this, I apprehend, arises more from inexperience of persecution in its native wilds than from any other cause, and which appears evident from the birds, when harassed and repeatedly fired at, soon becoming too cautious to admit of near approach any longer. Their habits also contribute to render them unwary, for being nocturnal feeders (like many others of the *Charadriadæ*), they are at rest and asleep during the greater part of the day, in which state also the Golden Plover (a wary bird when roused) will frequently admit of a close approach. As to the story of the Dotterel mimicking the actions of the fowler, by stretching out its leg, wing, or head, when he sets the example, it, without doubt, arose from the motions that they as well as other birds usually and most naturally make when roused from a state of repose; and which every one who attends to the habits of the feathered race must (in flocks of gulls, plovers, tringas, &c.) have frequently observed." The food consists principally of insects, slugs, and worms. For a long time it was doubted whether the Dotterel bred in this country, but these doubts are now removed, as the reader will find in the next paragraph. The rude nest is formed of lichens or moss, and the three or four lustreless olive-coloured eggs are sprinkled with large dots and numerous spots of deep brown-olive.

Mr. Selby notices the Dotterel as particularly abundant in Northern Asia and the eastern parts of Europe, and as inhabiting Siberia and the vast steppes of Tartary, frequently living in the vicinity of the salt lakes and marshes of that open region. He adds, that it is also found, during its winter migration, in Italy and Spain, and that the great body of these birds retires to the high latitudes of Northern Asia, Russia, and Lapland Alps to breed; but the flocks which pass along the eastern coast of our island are supposed to limit their flight to the upland districts and mountains of Sweden and Norway. Temminck states that it breeds in the north of Russia; also in Norway on the great bare plateaux of the mountains, and in no great number on the high mountains of Bohemia and Silesia at an elevation of from 4500 to 4800 feet. In this country, Sussex, Hampshire, Wiltshire, Berkshire, Cambridgeshire, Lincolnshire, Derbyshire, Yorkshire, and Northumberland possess it. Dr. Latham states that in the elevated district of Braemar, Aberdeenshire, these birds hatch their young on dry mossy ground near to and on the very summits of the highest parts, sometimes in the tufts of little short heather or moss. The female sits three weeks, and the young appear about the middle of July. Mr. Yarrell exhibited eggs of this bird, belonging to Mr. Heysham, of Carlisle, obtained on Skiddaw in the summer of 1835. Several pairs were breeding in the same locality. ('Zool. Proc.,' 1836.) Mr. Gould ('Birds of Europe') says, "The eggs of these birds are so difficult to obtain, that we only know one collector who possesses them. They are one inch eight lines long, by one inch two lines and a half in breadth, light olive-brown blotched and spotted with black: these specimens were procured from the Grampian Hills."



Dotterel (*Charadrius Morinellus*), in nuptial plumage.

They are excellent for the table when in season. Numbers are shot near Cambridge and Royston during their spring migration. We find 'Dotrels' charged at one penny each, a considerable sum in those days, in the 'Northumberland Household-Book,' and enumerated among the birds admitted to the high (his lordship's) table. They now find a ready sale in the London market at about six shillings a couple.

C. hiaticula, the Ringed Plover, Ring-Dotterel, Grand Pluvier à Collier of Temminck. It is found throughout the year on most of the shores of the British Islands, and is even more numerous on our own shores in winter than it is in summer.

C. Cantianus, the Kentish Plover, Pluvier à Collier Interrompu, Temminck. This bird was first obtained at Sandwich in Kent, and named by Dr. Latham in his 'General Synopsis of Birds.' Dr. Plomley of Maidstone states that it is very numerous in Romney Marsh at the present time. It arrives in April, breeds on the shingle, and departs in August. (Yarrell, 'British Birds,' vol. ii.)

C. minor, the Little Ringed Plover, or the Little Ring-Dotterel, Petit Pluvier à Collier, Temminck. Although on the continent of Europe by no means a rare bird, it has been obtained very rarely in England.

Hæmatopus. Bill long, strong, compressed; point very much compressed, chisel-like. Nostrils lateral, longitudinally slit in the groove of the bill. Feet strong, muscular; three toes directed forwards, middle toe united to the external one, up to the first joint, by a membrane, and to the internal toe by a small rudiment; toes bordered with the rudiment of a membrane. Wings moderate, the first quill longest.

Habits of the Genus.—The species live along the sea-shore, on the beach or sands; following the retreat of the waves, to gather such crustaceous or marine animals as they wash up. They assemble in great flocks for their migrations, but live solitarily during the time of pairing and incubation. Their nests are made in the herbage and in the marshy meadows near the sea, and they both run and fly with rapidity. Their cry is shrill and resounding. They moult twice, in autumn and spring, but the colours of the plumage scarcely change at all at those periods; the only marked difference observed at this change of plumage exists in the absence or presence of the white gorget. There is no difference in the sexes. (Temm.)

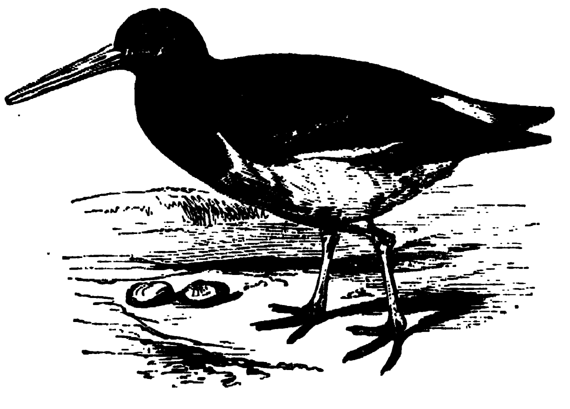
H. ostralegus (Linn.), the Oyster-Catcher. The male and female in winter plumage have the head, nape, upper part of the breast, back, wings, and extremity of the tail, deep black; a very marked gorget under the throat; rump, origin of caudal feathers and quills, transverse band on the wings, as well as all the lower parts, pure white; bill and naked circle round the eyes very bright orange; iris crimson; feet obscure red.

The young of the year have the black of the plumage clouded and bordered with brown; the white dirty; bill and naked circle of the eyes blackish-brown; iris brown; feet livid gray.

The summer or nuptial plumage has all the upper parts of the front of the neck of the same black as the wings, which black is more lustrous and with reflections. (Temm.)

This is L'Huîtrier, Pie de Mer, and Becasse de Mer, of the French; Boccaccia di Mare of the Italians; Marspitt and Strandskjura of the Swedes; Tialldur (fem. Tilldra) of the Icelanders; Kielder of the Feroe Islanders; Tield, Kield, Glib, and Strand-Skiure, of the Norwegians; Strand-Skade of the Danes; Geschackte Austernfischer of the Germans; Scholackster of the Netherlanders; Oyster-Catcher and Sea-Pie of the British; and Piogen y Môr of the Welsh.

It is common in Denmark, Sweden, and Norway, Russia, Siberia, and extending to Kamtchatka; the British Islands (where it is indigenous, and breeds), from the Scilly Isles to Shetland; common and resident in Ireland. Temminck states that this species also lives in North America, but that the Oyster-Catcher of Brazil and the whole of South America forms a distinct race. He adds that it also inhabits Japan. The Prince of Canino, in his 'Birds of Europe and North America,' however does not include it among the North American birds, but places opposite to it (in the American column) *Hæmatopus palliatus*, Temm. (*H. ostralegus*, Wils.; *H. Brasiliensis*. Licht.).



Oyster-Catcher, or Sea-Pie (*Hæmatopus ostralegus*).

It feeds upon small crustaceans, &c. and bivalve mollusks, which last its powerful bill and frame well enable it to open, so as to get at the contents. It will frequently wade far out, and trust to swimming back for its return. Their four eggs, of a bright hue, inclining to olive or yellowish stone-colour, spotted with ash-gray or dark brown, or blackish, are deposited in a shallow hole, scratched in the gravel or sand, and sometimes among the shingles of the beach, but most frequently among the herbage of marshy places near the sea. It can hardly be said to make a nest. Time of incubation three weeks. Young when first hatched covered with down of a brownish-gray colour. It is sometimes seen far up rivers and inland, where it feeds on earth-worms, &c., and fresh-water insects and mollusks. Easily domesticated in poultry-yards. Several used to be kept upon the grass in front of the Pavilion at Brighton, and there are some in the Gardens of the Zoological Society in the Regent's Park.

Strepsilas (Ill.). Bill moderate, hard at the point, strong, straight, of an elongated conical shape, slightly curved upwards; arête flattened; point straight, truncated. Nostrils basal, lateral, long, half-closed by a membrane, pierced through and through. Feet moderate; not much nakedness above the knee; three toes before and one behind; the three anterior toes united at the base by a very short membrane; the posterior toe articulated upon the tarsus. Wings acuminate; the first quill the longest. (Temm.)

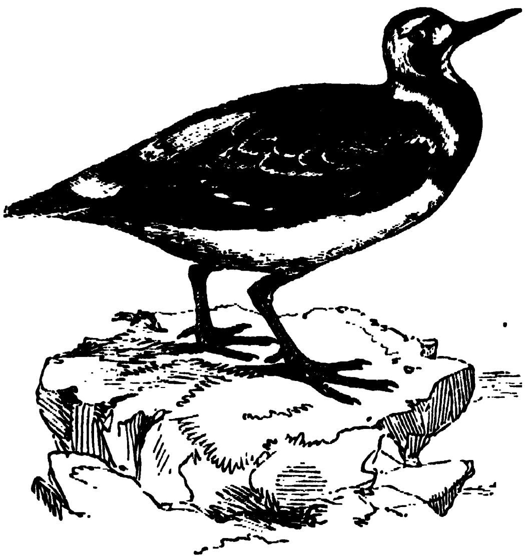
S. interpres (*Cinclus interpres*, G. R. Gray), the Turnstone. The very old male has the front space between the bill and the eye, a large collar on the nape, a part of the back, a longitudinal band and another transversal one upon the wing, upper coverts of the tail, middle of the breast, as well as the other lower parts, all of pure white; deep-black takes the shape of a narrow frontal band, which, passing before the eyes, is dilated below, where on one side it is directed on the lower jaw, and on the other dilating itself anew on the sides of the neck, it surrounds the throat, and forms a wide plastron in front of the neck and on the sides of the breast; top of the head reddish-white, striped longitudinally with black; upper part of the back, scapulars, and coverts of the wing bright chestnut red, sprinkled irregularly with large black spots; a large brown band on the rump; lateral quill of the tail pure white; bill and iris black; feet orange-yellow. Length 8 inches and 2 or 3 lines. The female differs only in having the shades less pure and the black less deep.

In this state of plumage the bird is *Tringa interpres* of Gmelin; *Morinella collaris*, Meyer; Turnstone or Sea-Dotterel of Edwards.

The young of the year have no trace of black nor of red chestnut. Head and nape of ashy-brown striped with deep-brown; white spots on the sides of the head and neck; throat and front of the neck whitish; feathers of the sides of the breast deep brown, terminated with whitish; the other lower parts and the back pure white; upper part of the back, scapulars, and coverts of the wings deep brown; all the feathers surrounded by a wide yellowish border; transverse band of the rump deep brown bordered with ruddy; feet yellowish-red. The black and white more regularly defined, in proportion as the bird advances in age.

In this plumage the bird is *Tringa Morinella*, Linn.; *Tringa interpres Morinella*, Gmel.; *Arenaria cinerea*, Briss.; the Turnstone, Pennant.

The young at the age of a year have the large plastron, or collar on the front of the neck and on the sides of the breast, marked out with black feathers, terminated by a narrow whitish border; summit of the head and nape brown, spotted with blackish-brown; back, scapulars, and coverts of the wings black, all the feathers surrounded by a ruddy border; a great black spot on the lateral tail-feather; the rest as in the adults. (Temm.)



Turnstone (*Strepsilas interpres*).

This is the Voltapietre of Savi; Steinwälzer of Brehm; and Huttan y Môr of the Welsh.

Geographical Distribution.—Very wide. Nova Zembla. Greenland, Winter Island, Felix Harbour, the coast between Victoria

Harbour and Fury Point—about the middle and end of June. Shores of Hudson's Bay and of the Arctic Sea up to the 75th parallel, where it breeds in June, quitting in September, halting in October on the shores of the Delaware, and proceeding farther south on the setting in of cold weather. The United States. The straits of Magellan. Cape of Good Hope. Japan, Sunda, the Molucca Islands, and New Guinea. Australia. In Europe, from Russia southward to Italy. Norway. Madeira. In this country it is found on the coasts from August to May, when it returns northward to breed. Stationary in Zetland, according to Dr. Fleming, who concludes that it breeds there.

The Turnstone, as its name implies, procures its food—small crustaceans, molluscous animals, &c.—by turning over with its strong bill the stones on the shore which shelter its prey. Mr. Hewitson found its nest on the coast of Norway placed against a ledge of rock, and consisting of nothing more than the dropping leaves of the juniper bush. Under a creeping branch of this shrub the eggs, four in number, of an olive-green colour, spotted, and streaked with ash-blue and two shades of reddish-brown, were concealed and sheltered.

CHARÆ'AS (Stephens), a genus of Moths of the family *Noctuidæ*. It has the following characters: Wings more or less denticulated; the posterior wings usually whitish in the males and brown in the females; palpi short, 2-jointed; maxillæ long; antennæ rather long, simple in the females, and more or less pectinated in the males; head small; thorax large, not crested; apex of the body furnished with a tuft of hairs in the males.

Several species of this genus have been found in England; their larvæ are naked, feed upon roots, and assume the pupa state underground.

C. Graminis (*Cerapteryx Graminis*, 'Cat. Brit. Lep. in Brit. Mus.'), the Antler Moth. It varies from an inch to an inch and a half in width, measured from tip to tip of the wings when expanded; it is of a brownish colour; the upper wings have a longitudinal white streak, which extends beyond the middle, and gives out three branches at the apex: touching this white line above there are two pale brown spots, and another of the same colour beneath, near the base of the wing; the apex of the wing has a row of pointed black spots, more or less distinct.

The caterpillar is of a brownish colour, with yellow streaks on the sides and back: it feeds upon grasses, and is exceedingly destructive to the pastures in Sweden. In England the insect is not so abundant; there is however an instance on record of its having committed considerable devastation in the north of England during the larva state. We allude to an account given by Mr. Wailes, in the second volume of the 'Entomological Magazine,' who observed a portion of the mountain of Skiddaw thus affected—their devastation causing the herbage to have a dry and parched appearance: the part affected comprised at least fifty acres, and extended some distance down the western side of the mountain; and so marked was the line that the progress made by the larvæ could be distinctly seen from the town of Keswick. Large flocks of rooks were observed to frequent the spot, and no doubt devoured immense numbers; the moths however appeared in great abundance in the month of August. From this same gentleman's observations we find that the history of the moth is also interesting. It appears to be their habit to fly from about half-past seven to half-past eight in the morning, during which time they are seen in some parts of the country in the utmost profusion; their appearance and disappearance are extremely sudden. The field in which Mr. Wailes observed them became in one moment a moving mass, and after about an hour not a single moth was to be seen, all having disappeared in a manner equally sudden: they fly about three or four inches from the ground, and thread their way with considerable rapidity through the stalks of grass. This moth is by no means abundant in the south of England: it departs a little from the characters of the genus in not having the wings notched.

The other species of this genus are *C. cespitis*, the Hedge-Rustic, *C. lutulenta*, the Barred-Feathered Rustic, *C. Æthiops*, the Black Rustic.

CHARD-BEET. [BETA.]

CHARLOCK. [SINAPIS; RAPHANUS.]

CHARR, or CHAR. [SALMONIDÆ.]

CHASMO'DIA, a genus of Coleopterous Insects of the section *Lamellicornes* (*Scarabæus*, Linn.), and sub-section *Xylophili* (Latreille). The species have the following characters:—Body rather convex and broad; scutellum large, somewhat triangular, equalling in length at least one-third of that of the elytra; the mesosternum is prolonged into a blunt point, and extends as far as the base of the femora of the anterior pair of legs; the mandibles are entire, and obtuse at the apex; maxillæ with only two teeth, and furnished with a tuft of fine hairs at the extremity; mentum elongated; elytra shorter than the abdomen, broad behind, and obtusely rounded. The male *Chasmodia* has the upper claw of the fore tarsi very broad and bifid, or divided at the apex; the inner claw is small and entire; the claws of the four posterior legs are entire, and of large size. The female has all the claws of small size; those of the anterior pair of legs simple; the four posterior legs have the outer claw bifid. The tarsi of the male are thicker than in the female, particularly those of the anterior pair of legs.

All the species of this genus are of large size, and may be readily distinguished from the *Cetoniæ* by their large scutellum and convex form, combined with their smooth and glossy appearance. The thorax is convex, and has the posterior margin considerably waved; the part joining the scutellum has a segment of a circle as it were cut out to admit the fore part of the latter, which is rounded; this character is also observed in the genus *Cetonia* and *Macraspis*, and affords a good point of distinction between these and the groups nearest allied. The genus *Macraspis* has also a very large scutellum, but differs in the tarsi and other parts. [MACRASPIS.]

Chasmodia viridis is about an inch in length and of a deep blue-green colour throughout, with the exception of the antennæ, the basal joints of which are pitchy-red, and the club is black.

There are four other species known, some of which are of a glossy brown or chestnut colour. They all inhabit South America. The species above named is common in collections from the Brazils.

CHATOESSUS, a genus of Fishes belonging to the family *Clupeidæ*. It resembles the common herring, but the first dorsal ray is prolonged in the filament. The species are inhabitants of the warmer seas.

CHATTERER. [BOMBYCILLA.]

CHAULIODUS, a genus of Natatorial Birds belonging to the family *Anatidæ*, instituted by Swainson. [DUCKS.]

CHAULIODUS, a genus of Fishes belonging to the Pike Family (*Esocidæ*). There is but one species, *C. Sloani*. It has two teeth in each jaw, across the other jaw when the mouth is shut. The dorsal fins are between the pectorals and ventrals. The first dorsal ray terminates in a filament. It has been taken at Gibraltar, is about 18 inches long, and of a deep green colour.

CHAULMOOGRA, a native Indian name for the bruised seeds of *Gynocardia odorata*. [PANGIACEÆ.]

CHAUNA. [PALAMEDEIDÆ.]

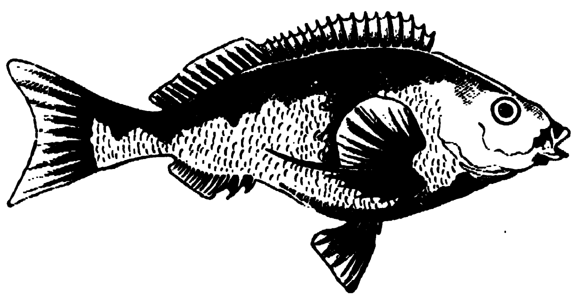
CHAVICA, a genus of plants belonging to the natural order *Piperaceæ*. It includes many of the species which are ordinarily referred to the genus *Piper*. [PIPER.]

CHEESE-RENNET, the *Galium verum* of botanists, which derives its popular name from having been formerly employed to curdle milk. [GALIUM.]

CHEILINUS. [LABRIDÆ.]

CHEILODA'CTYLUS, a genus of Fishes belonging to the section *Acanthopterygii* and family *Sciænidæ*. The mouth is small; dorsal fin with numerous spiny rays; lower rays of the pectoral fins simple and continued beyond the membrane.

Cheilodactylus monodactylus (*Chætodon monodactylus*, Carmichael, 'Linnæan Transactions,' vol. xii.) will serve to illustrate this genus. This fish is about 18 inches in length; the body is somewhat oval and compressed; the teeth are small and crowded; the pectoral fin is large, and has 15 rays, the six lower of which are simple and protrude beyond the membrane; the sixth ray from the bottom is very much elongated. The colour is olive, or bronze, with six dark stripes on the back; the fins are blackish, with the exception of the pectorals, which are amber-coloured.



Cheilodactylus monodactylus.

This species is very common on the coast of the small island of Tristan da Cunha, and feeds upon the *Fucus pyriferus*.

CHEILODI'PTERUS (Lacépède), a genus of Fishes belonging to the section *Acanthopterygii* and family *Percidæ*. The body is rather short; pre-operculum double-edged, the edges finely serrated; scales large, easily dislodged, continued on to the pre-operculum; the two dorsal fins widely separated.

The characters here detailed are those of the genus *Apogon*, from which the present genus differs chiefly in having the jaws furnished with long and pointed teeth. Three species of *Cheilodipterus* are known; they are all of small size, and furnished with slender longitudinal stripes. *C. octo-vittatus*, as its name implies, has eight stripes. *C. quinquelineatus* has five longitudinal black stripes, the ground colour of the body being silvery white; it is about four inches in length, and comes from the Society Islands. The third species, *C. Arabicus*, is of an olive-green colour above, and has the under parts silvery with a pinkish hue; this species has from 14 to 17 longitudinal stripes.

As an example of the genus *Apogon*, of which there are several species, we may notice the *Apogon Rex Mullorum*, or Roi des Rougets (Cuvier): this species rarely exceeds six inches in length, and is of a beautiful red colour with three large black spots on the back; one under each of the dorsal fins, and one towards the tail; the whole surface is also sprinkled with small black dots. The remaining species are also small, and most of them are of a red colour; a few have been found off the coast of Australia, but most of them frequent the Indian seas.

CHEIRACA'NTHUS, a genus of Fossil Fishes from the Old Red-Sandstone of Gamrie in Forfarshire and the Orkneys. (Agassiz.)

CHEIRANTHUS, a genus of plants belonging to the natural order *Cruciferæ*. This genus is known by possessing square or compressed siliques; a 2-lobed or capitate stigma; a calyx bi-saccate at the base; ovate compressed seeds in one series. The species are biennial or perennial herbs, or under-shrubs. The leaves are oblong, lanceolate, entire, or toothed. The flowers are arranged in racemes, and are of various colours—yellow, white, purple, or parti-coloured. Many of the species exhale a delicious odour, and are great favourites in gardens.

C. Cheiri, the common Wall-Flower, has lanceolate entire leaves, which are either smooth or covered with 2-parted appressed hairs; linear pods, and recurved lobes of the stigma. It is found wild throughout Europe, on old walls and in stony places, and almost constantly amongst the ruins of old castles. On this account it is a great favourite with poets, and is popularly regarded as an emblem of faithfulness in adversity. The general colour is a brown yellow, or, as a poet has called it, the "yellow wall-flower stained with iron-brown." It is however subject to considerable varieties of colour even in its wild state, and these are much increased by cultivation. On account of its scent it has been transferred from ruined walls to the flower-borders of gardens, and there, by the doubling of its flowers and the variations of its colours, a number of distinct varieties have been recorded. The following is a list of the most remarkable varieties found in gardens:—

α. *flore simplici.*	Single Yellow.
β. *flore pleno.*	Double Yellow.
γ. *maximus.*	Large-Flowered Yellow.
δ. *serratus.*	Large Yellow, saw-leaved.
ε. *patulans.*	Double Yellow, spreading.
ζ. *ferrugineus.*	Double Rosy.
θ. *varius.*	Double, variegated with purple and yellow.
ι. *flavescens.*	Large Double, pale yellow.
κ. *thyrsoideus.*	Bunch-Flowered, yellow.
λ. *gynantherus.*	Flowers with anthers changed into carpels.
μ. *hæmanthus.*	Single and Double, bloody-flowered.

The Wall-Flower is a common wild plant in Great Britain. It possesses the slight acridity of the order to which it belongs, and it has been recommended to sow it in pastures for the purpose of preventing rot in sheep. The wild flower has by some botanists been distinguished from the cultivated plant by the name of *C. fruticulosus*, but they are both the same.

Several other species of this genus have been described, and are occasionally found in collections in gardens in this country. In their cultivation the hardy shrubby species, such as the common Wall-Flower, may be propagated by cuttings, which soon strike root when planted under a hand-glass. Other perennial species will permit of growth by dividing the roots. The annual species may be sown in the open border or on rock-work, where they will flourish, and most of them will survive the winter in such a situation.

CHEIROGALEUS. [LEMURIDÆ.]

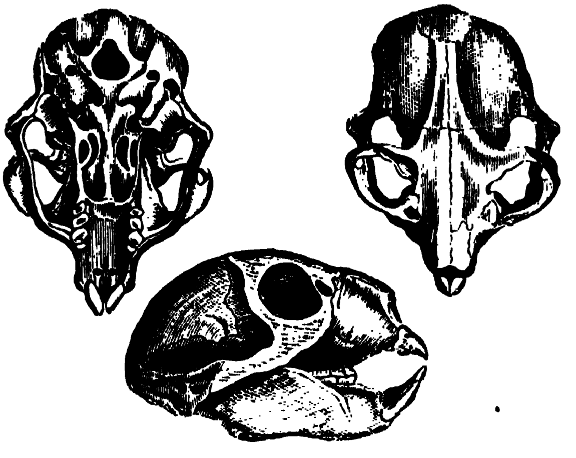
CHEIRO'LEPIS, a genus of Fossil Fishes from the Old Red-Sandstone of the Orkney Islands and Morayshire. The scales are very minute. (Agassiz.)

CHEIROMELES. [CHEIROPTERA.]

CHEI'ROMYS, one of the generic names given the Aye-Aye (which must not be confounded with the Ai, or Sloth [BRADYPUS], from which it very strongly differs in organisation), an animal discovered by Sonnerat at Madagascar, and described by him in the second volume of his 'Voyage aux Indes.' The name Aye-Aye it appears is an exclamation of the natives; and it is conjectured that it was given to this animal in consequence of a supposed resemblance to its cry. Sonnini, who formed the genus, censures Gmelin for denominating it *Sciurus Madagascariensis* (Madagascar Squirrel), because a quadruped of the latter genus really exists in Madagascar. Cuvier places the form next to the Flying Squirrels, Polatouches (*Pteromys*), and immediately before the Rats (*Mus*, Linn.), remarking that the lower incisors are much more compressed, and especially more extended from before backwards, than those of the squirrels, and resemble ploughshares (socs de charrue). The feet, he adds, have all five toes, of which four of those on each anterior extremity are elongated, the middle toe being much more slender than the others; in the hind feet, the great toe is opposeable to the others, so that in this respect the animal is among the Rodents what the Opossums (Sarigues) are among the Carnassiers. The structure of the head, he continues, is very different from that of the other Rodents, and has more relation to the *Quadrumana*.

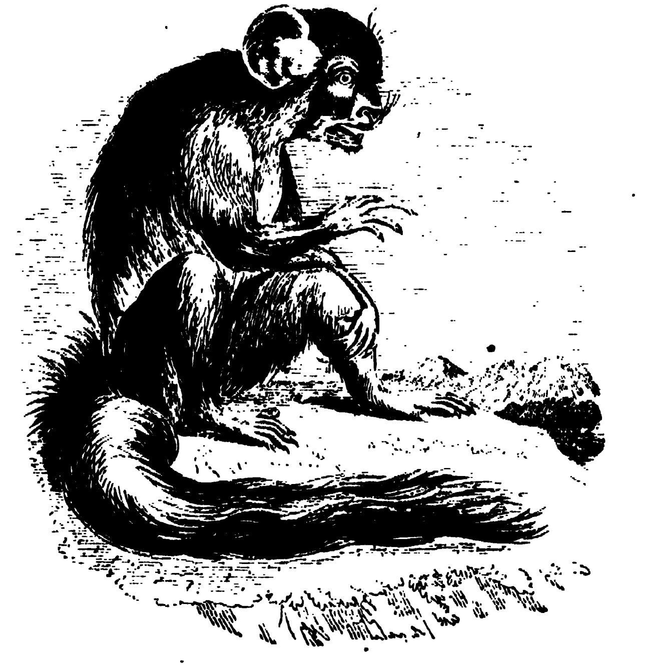
$$\text{Dental formula: incisors, } \frac{2}{2}\text{; molars, } \frac{4-4}{3-3} = 18.$$

Sonnerat says that the Aye-Aye, which is found chiefly if not exclusively on the western part of the island, does not approach any genus, but that it leans towards the Maki, the Squirrel, and the Ape. Its large and flat ears, he observes, resemble much those of a bat; and states that its principal character, and a very singular one it is, is the middle toe or finger of the fore foot, the two last joints of which are very long, slender, and denuded of hair. This member, he adds, is useful to it in drawing worms out of holes in the trees, and that it seems also to be of service in holding on to the branches of trees. He says that it appears to be a subterranean animal, and does not see during the day, and that its eye resembles in colour that of the owl. He describes it as being very slothful, but good tempered, remaining always at rest, and requiring a good deal of shaking to make it move. The subject of his observations lived two months upon no other nourishment than cooked rice, and it fed itself with its two fingers like the Chinese with their chopsticks. All the time M. Sonnerat had this animal alive, he never saw it carry its tail elevated like the squirrel. It always dragged.



Skull of Aye-Aye (*Cheiromys Madagascariensis*).

Buffon describes the colour as a musk-brown mixed with black and gray-ash. On the head, round the eyes, on the body, thighs and legs, the colour was deep musk, in which nevertheless black predominated upon the back and many parts of the body and legs. The tail was entirely black: the sides of the head, the neck, the jaw, and the belly were grayish. There were woolly hairs of this gray colour below the great black or white hairs, of two or three inches long, which were on the body and legs; but the legs and thighs were of a reddish-brown. Black predominated at the approach of the feet, which were covered with small hairs of that colour. The head was like that of a squirrel, and the ears large, naked, erect, and round at their extremities, with a wide opening. It is about the size of a common hare.



Aye-Aye (*Cheiromys Madagascariensis*).

This animal is the Aye-Aye Squirrel of Pennant, Shaw considered it to be a species of *Lemur*, and Schreber named it *Lemur psilodactylus*, a name adopted by Shaw.

CHEIRONECTES, or **CHIRONECTES** (Illiger), a genus of Marsupial animals. [MARSUPIATA.]

CHEIRO'PODA, *Cheiropeds*, a name proposed by Mr. Ogilby for all the mammiferous animals that are possessed of hands. The following is Mr. Ogilby's arrangement of his Cheiropeds:—

- CHEIROPEDS .. (Mammals with opposcable thumbs)
  - I. BIMANA .... *Homo.* (on the fore hands only)
  - II. QUADRUMANA .. (on both fore and hind hands)
    - SIMIÆ .... (and anthropoid teeth)
      - *Troglodytes.*
      - *Satyrus.*
      - *Hylobates.*
      - *Semnopithecus.*
      - *Colobus.*
      - *Cercopithecus.*
      - *Papio.*
      - *Cynocephalus.*
    - LEMURIÆ .... (and abnormal teeth)
      - *Lichanotus.*
      - *Propithecus.*
      - *Lemur.*
      - *Otolicnus.*
      - *Cheirogaleus.*
      - *Stenops.*
      - *Tarsius.*
      - *Cheiromys.*
      - *Galeopithecus.*
  - III. PEDIMANA .. (on the hind hands only)
    - SIMIADÆ .... (and anthropoid teeth)
      - *Cebus.*
      - *Ateles.*
      - *Mycetes.*
      - *Lagothrix.*
      - *Callithrix.*
      - *Aotus.*

Mr Ogilby states that observations, commenced in 1829 and continued for more than six years, have assured him that the non-opposeable character of the inner finger of the anterior extremities, which he first remarked in *Mycetes Seniculus*, is not confined to that genus, but extends throughout the whole of the genera of the South American monkeys, individuals of all of which have, he states, been seen by him in a living state. In none of them consequently, he observes, does a true thumb exist on the anterior limbs; and he considers that it follows as a further consequence that the whole of them have been hitherto incorrectly referred to the *Quadrumana* by zoologists generally. The following extract from the 'Proceedings of the Zoological Society,' for 1836, will explain the views of this naturalist:—

"Of the eight natural genera which include all the known monkeys of the western hemisphere, one, *Ateles*, is entirely destitute of a thumb, or has that member existing only in a rudimentary form beneath the skin. In five others, *Mycetes*, *Lagothrix*, *Aotus*, *Pithecia*, and *Hapale*, the anterior thumbs (using the ordinary expression for them) are placed absolutely on the same line with the other fingers, are of the same form with them, act invariably in the same direction, and are totally incapable of being opposed to them. In the two remaining genera, *Cebus* and *Callithrix*, the extremities of the anterior limbs have a greater external resemblance to the hands of man and of the monkeys of the Old World: the internal finger is placed farther back than the general line of the other fingers, and has on that account, when superficially noticed, the semblance of being opposed to them; but, as has been correctly observed by D'Azara with reference to *C. capucinus*, it is less separated than in man: it is besides of precisely the same slender form with the rest, is weaker than them, absolutely without power of opposition to them, and habitually acts in the same direction with them. The impression derived from contemplating the hands of the Old World monkeys might induce the belief that the extremities of the *Cebi* are similarly constituted; but if the knowledge that in *Mycetes*, *Pithecia*, &c., there are no opposeable thumbs leads to a close observation of the anterior extremities of the *Cebi*, it will be found that they do not act as hands and cannot be considered as possessing the powers of those organs. From innumerable observations of many species of that genus, Mr. Ogilby states that it was very evident, notwithstanding the fallacious appearance occasioned by the backward position of the organ, that they had not the power of opposing the thumbs to the other fingers in the act of prehension; and in fact their principal power of prehension seems to be altogether independent of the thumb, for generally speaking that member was not brought into action at all, at least not simultaneously with the other fingers, but hung loosely on one side, as Mr. Ogilby has seen it do in like circumstances in the Opossums, Phalangers, and other arboreal mammals: when actually brought into play however the thumb of the *Cebi* invariably acted in the same direction as the other fingers. *Cebus* consequently agrees in the character of non-opposeableness of thumb with the nearly allied genera. And in this hitherto unsuspected peculiarity zoologists obtain a far more important character by which to distinguish the monkeys of the Old and New World than that hitherto relied on, the comparative thickness of the septum narium, or than the accessory aids afforded by the absence of cheek-pouches and callosities. Hence, according to Mr. Ogilby, as the monkeys of America have now been ascertained to be destitute of anterior hands, they can no longer be included among the *Quadrumana*, and he proposes in consequence to regard them as *Pedimana*. He considers that the latter series, the monkeys of America, form a group parallel to that of the monkeys of the Old World among the *Quadrumana*: and viewing the *Quadrumana* as consisting of two primary groups, that of which *Simia* forms the type, and the *Lemuridæ*, he proceeds to analyze the *Pedimana*, in order to determine whether any group analogous to the Lemurs exists in it. He finds such a group in the association of the genera *Didelphis*, *Cheironectes*, *Phalangista*, *Petaurus*, and *Phascolarctos* (together with a new genus, *Pseudochirus*, which he has found it necessary to separate from *Phalangista* as at present constituted); and for this association he uses the name of *Didelphidæ*. Aware that the modifications observable in the dentary systems of these several genera have been regarded by many zoologists as betokening a difference of regimen, which has led to their being viewed as constituting distinct families, he in the first place states, as the result of his observation of the habits of the numerous species of all these genera which have been from time to time exhibited in the Society's Gardens, that there is little or no difference in this respect between the Opossums and Phalangers, but that all are equally omnivorous; and then proceeds to discuss the modifications that exist among them in the number and forms of the several kinds of teeth, which are not in his estimation so very different in reality between the Opossums and Phalangers as they appear to be at first sight. In further support of his opinion that this association of genera forms a natural family, Mr Ogilby refers to the gradual and uninterrupted transition from the naked-prehensile-tailed Opossums of South America, through the equally naked-tailed Couscous, *Balantia*, of the Indian Isles, to the true Phalangers; and from these to the Petaurists directly on the one hand, and by means of the Pseudocheirs to the Koalas on the other.

"On the prehensile power of the tail Mr. Ogilby particularly insists as on a faculty possessed by the greater number of the *Pedimana*, and as one which is in truth almost confined to them; only three known genera belonging to other groups, *Synetherus*, *Myrmecophaga*, and *Cercoleptes*, being endowed with it. He remarks on this faculty as on one of considerable importance, affording as it does in some degree a compensation for the absence of opposcable thumbs on the anterior limbs. Combined with the prehensile tail, in every known instance, whether among the *Pedimana* or in other groups, is a slowness and apparent cautiousness of motion, not observable in any of the *Quadrumana*, except in the *Nycticebi*. In none of the true *Quadrumana* is the tail prehensile.

"Another evidence of the distinctness, as two groups, of the *Quadrumana* and the *Pedimana* is furnished by their geographical distribution. The *Quadrumana* are strictly confined to the limits of the Old World; the *Pedimana* almost as exclusively to the New World, for Mr. Ogilby considers the continent of Australia to belong more properly to America than to Asia. The very few apparent exceptions that occur to this latter position are in the presence of some species of Phalangers in the long chain of islands that connect the south-eastern shores of Asia with the north-eastern coast of Australia; islands which may in truth be fairly regarded as belonging partly to the one and partly to the other, and the productions of which might consequently be expected to partake of the character of both.

"Mr. Ogilby subsequently adverts to another Pedimanous animal, the Aye-Aye of Madagascar, constituting the genus *Cheiromys*; respecting the affinities of which he speaks with hesitation, because, having never had an opportunity of examining the animal itself, he is acquainted with its characters only at second hand. He is however disposed to regard it as representing a third group among the *Pedimana*, to be placed in a station intermediate between the Monkeys of the New World and the *Didelphidæ*. With the latter he would, in fact, be disposed to associate it, were it not destitute of the marsupial character which belongs to all the other animals comprised in that group. In some of the *Didelphidæ*, the Phalangers and Petaurists especially, there is a marked approximation to that rodent form of incisor teeth which obtains in *Cheiromys*, and which has hitherto been regarded as especially attaching to it an abnormal character.

"Man is the only other animal furnished with hands, and however distinct he may be as regards his moral and intellectual powers, he must, zoologically, be considered on physical grounds. By the structural characters he becomes associated with all those of which mention has previously been made in Mr. Ogilby's communication; although he unquestionably constitutes among them a peculiar group, sensibly exalted above the rest, as well as above all other Mammals."

CHEIROPTERA (χείρ, a hand, πτερόν, a wing), the name of a natural family or division of Mammiferous Animals; the Bats or Flitter-Mice of the English; Fledermäuser of the Germans; *Vespertiliones* of the Latins; Pipistrelli and Nottoli of the Italians; Chauve-souris of the French.

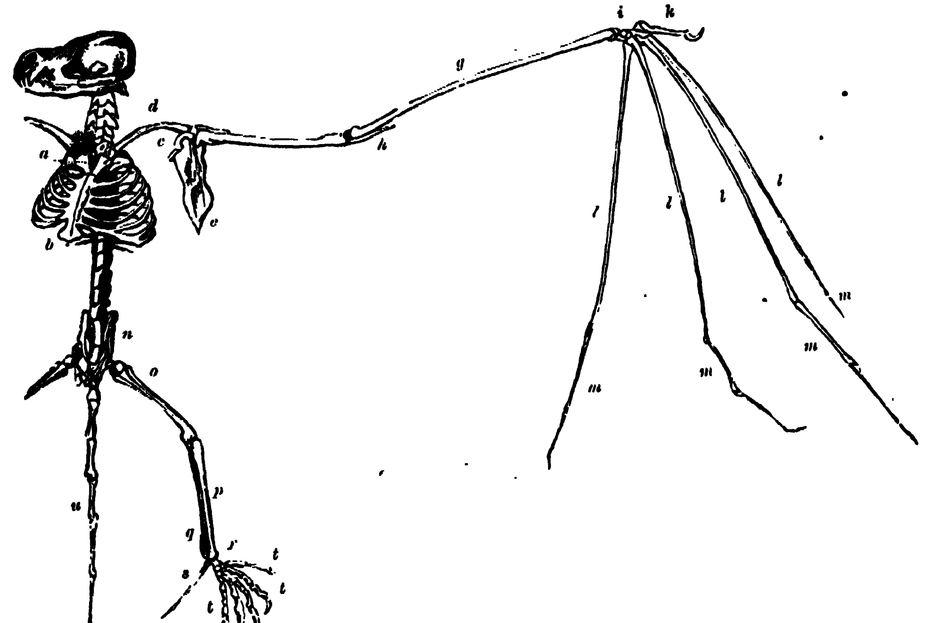
The animals belonging to this wing-handed family embrace those which come under the genus *Vespertilio* of Linnæus. They all have the faculty of sustained flight, and their organisation and habits point them out as a separate and well-defined group, distinguished by a folding extension of the membranous skin, which, rising from the sides of the neck, is spread between their fore feet and their fingers.

Organisation.—Skeleton.—The skull is thin, and there is a marked difference between that of the so-called Frugivorous group (*Pteropus* and *Cephalotes*) and the true or Insectivorous Bats, the former being much more elongated than the latter. The bony tentorium, so strongly developed in the majority of the *Carnivora*, is entirely absent; but there is a considerable development of the auditory portion of the temporal bone. The occipital bone is remarkably narrow. The superior maxillary is very much elongated, particularly in the so-called Frugivorous order, a term which we would change for Omnivorous, for their well-developed sharp canines, and the structure of some of their other teeth, would seem to be more trenchant than fruit-eating habits alone would require; and indeed Cuvier, in the last edition of the 'Règne Animal,' says of the genus *Pteropus*, "they live principally on fruit, of which they destroy a great deal; but they know, nevertheless, how to pursue birds and small quadrupeds;" and we think it highly probable that they occasionally prey on the large insects which are found in the climates they inhabit. All the family have four great canine teeth, but there is considerable difference between the molars of the fruit-eating section and of that whose diet is confined entirely to insects, the crowns of the former being comparatively blunt, and hollowed out or grooved lengthwise, while those of the latter are shorter and sharper, and beset with points. The molars vary in number in the different genera, the smallest development being three in each jaw, and the largest five above and six below, or vice versâ. The incisors set in the small and short intermaxillary bones vary also in the different genera. The smallest number in the upper jaw is two, and the largest four; the smallest number is also two in the lower jaw, and the largest six. The atlas is of considerable size, but the dentata is not large. The greatest number of the dorsal vertebræ is twelve, the smallest eleven. The canal for the spinal cord is large in these vertebræ. The lumbar vertebræ vary in number; the smallest number is four, the largest seven. The ossa coccygis are slender and elongated: their use seems only to be to assist (somewhat like a spreat) in spreading the interfemoral portion of the membranes, by the aid of which the animal sails in the air; their smallest number is six, and their largest twelve; for in the majority the tail extends to the margin of the membrane, while in some it protrudes beyond it, and in others it does not reach more than half way. In *Pteropus* there is no trace of these bones.

The ribs are remarkably long, except the first pair, which is very short, and remarkably broad, especially in the cartilage, which is ossified; and the sternum is highly developed, as might be expected from the exigencies of the animal. The anterior portion is expanded laterally into what is termed the manubrium, which seems to be largest in the Horse-Shoe Bat (*Rhinolophus*), forming a suitable point of attachment for the strong long arched clavicles, which are articulated both to the sternum and scapula; the latter is very large and elongated, and the lower surface is very concave. The fossæ for the strong muscles, both above and below the spine of this bone, are deeply marked. The habits of the animal required an ample development of these parts to give the shoulder the required solidity for working the mechanism of the wing, and we accordingly find the strength thrown into the sternum, clavicles, and scapula. But these same habits would have rendered the rotatory motion of the fore-arm worse than useless, for such a disposition would have weakened the power of the limb in beating the air with the extended membrane. We accordingly find that this power is absent: the ulna, indeed, is remarkably small, and in some the bone is merely rudimentary, forming a mere flat process, only partially separated from the radius; there is no olecranon (elbow). The humerus is long, slender, and cylindrical, and the head of the bone large and round. The structure of the wrist is peculiar: first come two bones next to the radius, and on these that bone rests; one of these is very large, and the other very small—the second series consists of the usual four bones; but it is in the bones of the metacarpus and of the fingers that the adaptation of the osseous parts of the animal to its necessities is, perhaps, most strongly shown. These, with the exception of the phalanges of the thumb, are greatly elongated, and run outwards and downwards to the edge of the wing-membrane, something after the fashion of the whalebones that assist in spreading an umbrella. The first finger is the shortest, and extends to the upper angle of the outer edge of the membrane; the second is generally the longest, and the third and fourth nearly of a length; the last three descend to the lower edge of the membrane. The pelvis is straight and lengthened, and rather wider below than it is above, the ilia being very narrow and elongated. The ossa ischii approach even to the contact of their tuberosities, and in some examples touch the ossa coccygis. The ossa pubis, in some species, recede from each other, the intermediate space being filled by a ligament; and in others these bones touch each other in the male, and are separated in the female. The sacrum and ilia are anchylosed early in life. The lower extremities do not offer any very striking differences from those of other mammifers, excepting that the thighs being directed outwards, the bones of the leg are partially turned round as it were (the fibula appearing at the inner side of the tibia, and a little posterior to that bone), and that there is a singularity about the heel. An elongated delicate bony process is given off from the back part of the foot, is inclosed in the margin of the interfemoral membrane, and proceeds about halfway to the tail. Cuvier thought this a portion of the os calcis; Daubenton, that it was a distinct bone; and Meckel, that it is only a development of the tuberosity of the bone, disunited from its body.

Besides the difference of the molar teeth in the Fruit-Eating (or Omnivorous) and the Insectivorous Bats, the stomach and intestines present a remarkable corresponding variance. The stomach of the former is very complicated, and the intestines very long: in *Pteropus*, for example, they are seven times as long as the body. In the latter the stomach is very simple, and merely divided into the cardiac and pyloric portions, and the intestines are not more than twice the length of the body. These differences, together with that of the greater or less development of the tail, which is powerful, generally speaking, in the true Insectivorous Bats, and either absent, rudimentary, or comparatively inefficient in the Fruit-Eaters, which last do not require to turn so rapidly as the desultory flight of the prey of the former makes it necessary for them to do, form, it is true, a marked distinction between the two groups; but we are, notwithstanding, of opinion that very few bats confine themselves entirely to a vegetable diet.

The nervous system of *Cheiroptera* is fully developed. The senses of taste, smell, sight, and hearing are acute. The external ear is very large in many of the species. The sense of touch, or a sense analogous to it, must be highly developed. Spallanzani—we cannot



Skeleton of Bat (*Vespertilio murinus*).

a, manubrial bone; *b*, xiphoid cartilage; *c*, coracoid bone; *d*, clavicle; *e*, shoulder-blade; *f*, humerus; *g*, radius; *h*, rudiment of ulna; *i*, carpus (wrist); *k*, metacarpus of thumb, terminated by a hook-shaped phalanx; *l*, metacarpal bones of the fingers; *m*, digital phalanges; *n*, pelvis; *o*, femur; *p*, tibia; *q*, fibula; *r*, tarsal bones of foot; *s*, styliform appendage to os calcis; *t*, metatarsus and toes; *u*, tail.

compliment him on his humanity—extracted the eyes of bats and covered the empty sockets with leather; yet, in this condition, they flew round his room, avoiding the sides, never striking against anything, and flying out of the door without touching the door-case. In flying through a sewer which made a right angle, they turned at the proper point, though at a distance of two feet from the walls. They found their resting-place on a cornice, and flew through threads, suspended perpendicularly from the ceiling, without touching them, though scarcely farther apart than would admit their extended wings; and they avoided all obstacles with equal facility when the whole head was covered with varnish. But, according to the experiments of Carlisle, the British Long-Eared Bat was entirely at a loss, if, when blinded, its ears were stopped, for in that condition the blinded bats struck against the sides of the room, and seemed to be quite unaware of their situation. The following additional note to the English translation of Blumenbach however corroborates Spallanzani:—"Bats have been supposed to possess a peculiar power of perceiving external objects, without coming actually into contact with them. In their rapid and irregular flight, amidst various surrounding bodies, they never fly against them; yet it does not seem that the senses of hearing, seeing, or smelling, serve them on these occasions, for they avoid any obstacles with equal certainty when the ear, eye, and nose, are closed. Hence naturalists have ascribed a sixth sense to these animals; it is probably analogous to that of touch. The nerves of the wing are large and numerous, and distributed in a minute plexus between the integuments. The impulse of the air against this part may probably be so modified by the objects near which the animal passes, as to indicate their situation and nature." Cuvier, in his 'Leçons d'Anatomie Comparée,' had, in a great measure, solved the mystery by observing, as is remarked in the note just quoted, that the whole surface of the flying membrane, on both sides, is endowed with extraordinary sensibility, and may be considered as one continuously expanded organ of touch. Nor is this the only peculiarity connected with the integument of the bats, for in the genus *Nycteris* there exists a power of inflation to such a degree, that when the faculty is exerted the animal looks, according to Geoffroy, like a little balloon fitted with wings, a head, and feet. The subcutaneous tissue is the part inflated, and as the skin adheres to the body at particular points only, the connection being by means of loose cellular membrane, spaces are left which can be filled with air at the will of the *Nycteris*, through the cheek pouches, which are perforated at the bottom so as to communicate with those spaces. When the *Nycteris* wishes to inflate its skin, it draws in its breath, closes its nostrils, and transmits the air through the perforations of the cheek pouches to the subcutaneous spaces, and the air is prevented from returning by the action of a sphincter, which closes those openings, and by valves of considerable size on the neck and back.

The organs of reproduction nearly approach those of the *Quadrumana* and man in many respects. In the female two teats are placed on the breast as in man and in the *Quadrumana*.

The *Cheiroptera* are widely spread over the globe. They are to be found in the Old and New World and in Australia. A tolerably temperate climate seems necessary for them, and the greatest development of the form takes place in warm countries. Sir John Richardson ('Fauna Boreali-Americana') notices two species, *Vespertilio pruinosus* (Say) caught at Cumberlard House, on the Saskatchewan in 54° N. lat., and *Vespertilio subulatus* (Say), which he observes is the most common species near the eastern base of the Rocky Mountains on the upper branches of the Saskatchewan and Peace River.

Habits.—Generally speaking they remain in concealment during the day in caverns, ruinous buildings, hollow trees, and such hiding places, and flit forth at twilight or sunset to take their prey. White, in his 'Selborne,' thus describes the mode of feeding a tame bat: "It would take flies out of a person's hand; if you gave it anything to eat it brought its wings round before the mouth, hovering and hiding its head, in the manner of birds of prey when they feed. The adroitness it showed in shearing off the wings of flies, which were always rejected, was worthy of observation, and pleased me much. Insects seemed to be most acceptable, though it did not refuse raw flesh when offered; so that the notion that bats go down chimneys and gnaw men's bacon, seems no improbable story. While I amused myself with this wonderful quadruped I saw it several times confute the vulgar opinion, that bats, when down on a flat surface, cannot get on the wing again, by rising with great ease from the floor. It ran, I observed, with more dispatch than I was aware of, but in a most ridiculous and grotesque manner." The Large-Eared Bats, collected by Carlisle, refused, according to Shaw, every species of food for four days, as did a large number which were afterwards caught and preserved in a dark box, for above a week. During the day-time they were extremely desirous of retirement and darkness; and, while confined to the box, never moved or endeavoured to get out the whole day; and when spread on the carpet they commonly rested some minutes, and then, beginning to look about, crawled slowly to a dark corner or crevice. At sunset the scene was quite changed: every one then endeavoured to scratch its way out of the box; a continual chirping was kept up, and no sooner was the lid of their prison opened than each was active to escape; either flying away immediately, or running nimbly to a convenient place for taking wing. When these bats were first collected, several of the females had young ones clinging to their breasts in the act of sucking. One of them flew with perfect ease, though two little ones were thus attached to her, which weighed nearly as much as the parent. All the young were devoid of down, and of a black colour. One of the most interesting and detailed accounts of the habits of these animals is that made by Mr. Daniell to the Zoological Society of London. The bats consisted of two species, the Pipistrelle (*Vespertilio Pipistrellus* of Geoffroy) and the Noctule (*Vespertilio noctula* of Schreber). Mr. Daniell stated that in July, 1833, he received five specimens, all pregnant females, from Elvetham in Hampshire. Many more were congregated together with them in the ruins of the barn in which they were taken, but all the rest escaped. They had been kept in a tin powder canister for several days, and on being turned loose into a common packing-case, with a few strips of deal nailed over it to form a cage they exhibited much activity, progressing rapidly along the bottom of the box, ascending by the bars to the top, and then throwing themselves off as if endeavouring to fly. They ate flies when offered to them, seizing them with the greatest eagerness, and devouring them greedily, all of them congregating together at the end of the box at which they were fed, and crawling over, snapping at, and biting each other, at the same time uttering a grating kind of squeak. Cooked meat was next presented to them, and rejected; but raw beef was eaten by them with avidity, and with an evident preference for such pieces as had been moistened with water. This answered a double purpose; the weather being warm numbers of the Blue-Bottle Flies (*Musca vomitoria* of Linnæus) were attracted to the meat; and on approaching within range of the bats' wings were struck down by their action, the animal itself falling at the same moment with all its membranes expanded, and cowering over the prostrate fly, with its head thrust under in order to secure its prey. When the head was again drawn forth the membranes were immediately closed, and the fly was observed to be almost invariably taken by the head. Mastication appeared to be a laboured operation, consisting of a succession of eager bites and snaps, and the sucking process (if it may be so termed), by which the insect was drawn into the mouth, being much assisted by the looseness of the lips. Several minutes were employed in devouring a large fly. In the first instance the flies were eaten entire, but Mr. Daniell afterwards observed detached wings in the bottom of the box. These however he never saw rejected, and he is inclined to think that they are generally swallowed. A slice of beef attached to the side of the box was found not only to save trouble in feeding, but also by attracting the flies to afford good sport in observing the animals obtain their food. Their olfactory nerves appear to be very acutely sensible. When hanging by their posterior extremities, and attached to one of the bars in front of the cage, a small piece of beef placed at a little distance from their noses would remain unnoticed; but when a fly was placed in the same situation they would instantly begin snapping after it. The beef they would eat when hungry, but they never refused a fly. In the day-time they sometimes clustered together in a corner; but towards evening they became very lively, and gave rapid utterance to their harsh grating notes. One of them died on the fifth day after they came into Mr. Daniell's possession; two on the fourteenth; the fourth survived until the eighteenth; and the fifth until the nineteenth day. Each was found to contain a single fœtus.

On the 16th of May, 1834, Mr. Daniell procured from Hertfordshire five specimens of *Vespertilio noctula*—four females and one male. The latter was exceedingly restless and savage, biting the females, and breaking his teeth against the wires of the cage, in his attempts to escape from his place of confinement. He rejected food, and died on the 18th. Up to this time the remaining four continued sulky; but towards evening they ate a few small pieces of raw beef in preference to flies, beetles, or gentles, all of which were offered to them; only one of them, however, fed kindly. On the 20th one died, and on the 22nd two others. The survivor was tried with a variety of food, and, evincing a decided preference for the hearts, livers, &c. of fowls, was fed constantly upon them for a month. In the course of this time large flies were frequently offered to her, but they were always rejected, although one or two May Chafers (*Melolontha vulgaris*) were partially eaten. In taking the food the wings were not thrown forward as in the Pipistrelle, and the food was seized with an action similar to that of a dog. The water that drained from the food was lapped, but the head was not raised in drinking, as Mr. Daniell had observed it to be in the Pipistrelle. The animal took considerable pains in cleaning herself, using the posterior extremities as a comb, parting the hair on either side from head to tail, and forming a straight line along the middle of the back. The membrane of the wings was cleaned by forcing the nose through the folds and thereby expanding them. On the 20th of June this specimen produced a young one. At the time of its birth the young was larger than a new-born mouse, and its hind legs and claws were remarkably strong and serviceable, enabling it not only to cling to its dam, but also to the deal sides of the cage. On the 24th the animal took her food in the morning, and appeared very careful of her young, shifting it occasionally from side to side to suckle it, and folding it in the membranes of the tail and wings. On these occasions her usual position was reversed. In the evening she was found dead, but the young was still alive, and attached to the nipple, from which it was with some difficulty removed. It took milk from a sponge, was kept carefully wrapped up in flannel, and survived eight days, at the end of which period its eyes were not opened, and it had acquired very little hair. All the species of *Cheiroptera* hybernate.

Systematic Arrangement.—Among the ancients Aristotle says but little about thè Bat, and Pliny is considered to have placed it among the Birds, none of which, he observes, with the exception of the Bat, have teeth. ('Hist. Nat.' lib. xi. c. 37.) Again (lib. x. c. 61), he notices it as the only winged animal that suckles its young, and observes on its embracing its two little ones and flying about with them. In this arrangement he was followed by the older of the more modern naturalists; Belon, Gesner, and Aldrovandus, for instance. The former, after expressing some doubt, places it at the end of the Night-Birds, in his 'Histoire de la Nature des Oyseaux' (folio, 1555), and it occupies the same position in the small 4to (1557), with the following quatrain:—

> "La Souris Chauve est un oiseau du nuict,
> Qui point ne pond, ains ses petits enfante,
> Lesquels de laict de ses tetins sustante,
> En petit corps grande vertu reluit."

The Bat (*Attalcph*, 'bird of darkness') was one of the unclean animals of the Hebrews (Deut. xiv. 18), where it is placed among the forbidden birds.

Under the title 'Vespertilio,' the fourth and last genus of his first order, *Primates*, Linnæus arranged all the *Cheiroptera* known to him, and the number of species recorded in the twelfth edition of the 'Systema Naturæ' amounts only to six. In the thirteenth edition (Gmelin's) the number of species given amounts to twenty-three. This edition was printed in 1789, and few families afford stronger evidence of the great influx of the new species within the last five-and-forty years than is to be found in the numbers of *Cheiroptera* which have been described within that period. Of English bats alone Jenyns enumerates sixteen species, and the general numbers have been increased more than six-fold. Cuvier made the *Cheiroptera* the first family of his third order of Mammifers, placing them next to the *Lemuridæ*, which close his second order, *Quadrumana*. Jenyns, in his 'Manual of British Vertebrate Animals,' places them under the order *Primates*, which he makes the second in his arrangement of British *Mammalia*, the *Feræ* being the first; and they come immediately after the shrews and the hedge-hog.

The classification of the family we propose to follow, is taken in great measure from the French authors, and adopted by Desmarest and Lesson. *Galeopithecus*, which is the type of the first tribe of *Cheiroptera*, according to Lesson, we have removed, in accordance with the opinions of other zoologists, from this family; and though the *Vespertilionidæ* may be divided into two natural sections, the Insectivorous Bats and the Fruit-Eaters, we have, in consideration of the gradual shades of form when the numerous species are brought under observation, followed M. Lesson's arrangement, with the exception above alluded to.

VESPERTILIONIDÆ.

§ 1. *Istiophori*, Spix.

Bats having a membrane in form of a leaf upon the nose. Molar teeth with sharp tubercles.

1. Sub-Family, *Phyllostomatina*.

Nose-leaf simple, solitary, or unequal, the forefinger composed of two joints.

Phyllostoma, Geoff. Four incisors above and the same number below. Canine teeth very strong. Nose supporting two nasal crests, one leaf-like, the other like a horseshoe. Ears large. Internal oreillon dentelated. Tongue bristled with papillæ. Tail variable in length, sometimes none. The dental formula is—

$$\text{Incisors, } \frac{4}{4}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{5-5}{5-5} = 32.$$

a. Tail shorter than the interfemoral membrane.

P. crenulatum. The borders of the nasal leaf are dentelated, the end of the tail free. Locality unknown.

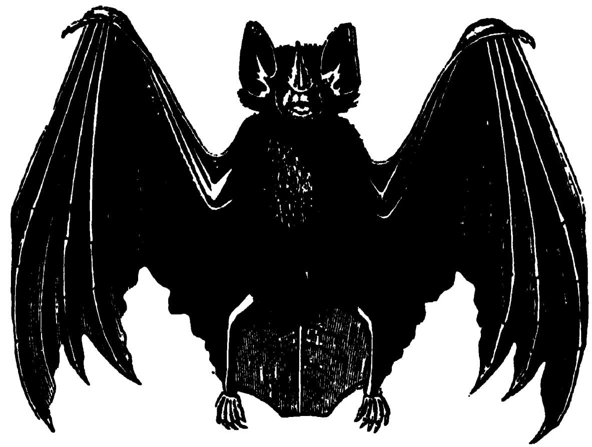
b. No Tail.

P. perspicillatum, Geoff. *Vespertilio perspicillatus*, Linn.

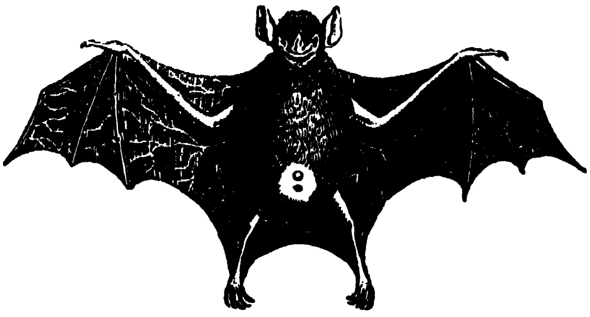
Vampirus, Geoff. and F. Cuvier. The same character as in the *Phyllostomata*, with the exception of the dental formula, which is as follows:—

$$\text{Incisors, } \frac{4}{4}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{5-5}{6-6} = 34.$$

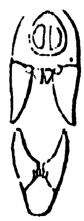
V. Spectrum. This is the celebrated Vampire Bat of which so many bloodthirsty stories have been told; the *Phyllostoma Spectrum* of some authors, *Vampirus sanguisuga* of others, the Andira-guaca of Piso, and the *Vespertilio Spectrum* of Linnæus. The nose-leaf is entire, higher than it is wide, although it becomes widened at the base. The following is Piso's account of its habits:—"They seek out every kind of animal, and suck their blood. But in Maranhan (Maranham) there is a certain kind of bats which approach by night the naked feet of men, and wound them with their rostrum, for the sake of sucking human blood. The bite is so slight and subtle that the wounded do not feel it before the bed covered with blood gives token of the wound. So great a quantity of blood flows from the envenomed bite that it can only be stopped with difficulty, and the peril is imminent unless a cure by the prescribed remedies be effected. The inhabitants first wash these wounds with hot sea-water, and afterwards apply hot ashes, or even cautery, if the blood be not stopped." Captain Stedman, who states that he was bitten, thus describes the operation:—"Knowing by instinct that the person they intend to attack is in a sound slumber, they generally alight near the feet, where, while the creature continues fanning with its enormous wings, which keeps one cool, he bites a piece out of the tip of the great toe, so very small indeed that the head of a pin could be scarcely received into the wound, which is consequently not painful; yet through this orifice he continues to suck the blood until he is obliged to disgorge. He then begins again, and thus continues sucking and disgorging till he is scarcely able to fly; and the sufferer has often been known to sleep from time into eternity. Cattle they generally bite in the ear, but always in places where the blood flows spontaneously. Having applied tobacco-ashes as the best remedy, and washed the gore from myself and my hammock, I observed several small heaps of congealed blood



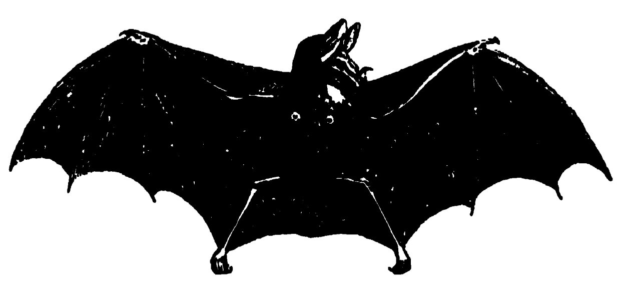
Phyllostoma crenulatum.



Phyllostoma perspicillatum.



Teeth of Vampire Bat (*Vampirus Spectrum*).



Vampire Bat (*Vampirus Spectrum*).

all round the place where I had lain, upon the ground, on examining which the surgeon judged that I had lost at least twelve or fourteen ounces during the night." This is sufficiently circumstantial, and the narrative is assisted by Mr. Wood, who quotes the passage in his 'Zoography,' and who informs us that "it is said to perform the operation by inserting its aculeated tongue into the vein of a sleeping person with so much dexterity as not to be felt; at the same time fanning the air with its large wings, and thus producing a sensation so delightfully cool that the sleep is rendered still more profound, and the unfortunate person reduced almost to death before he awakes." And the same author further informs us that "there is reason to believe that this thirst after blood is not confined to the bats of one continent, nor to one species, since at Java they seldom fail to attack those persons who lie with their feet uncovered." The same sort of stories are to be found in most books of Natural History up to a late period. Wood's work was published in 1807, and the tales are continued in Bewick in the edition of 1820. Cuvier, in the last edition of the 'Règne Animal' (1829), says, "They have accused this species of having caused men and beasts to perish by sucking them, but it contents itself with making very small wounds, which may sometimes become envenomed by the climate." Lesson (1827), in his notice of the genus, says, "The single American species is celebrated by the fables with which they have accompanied its history." Dr. Horsfield, who paid particular attention to the Javanese Bats, does not say a word of their blood-thirsty propensities. That some of the *Phyllostomata* suck the blood of animals as well as the juices of succulent fruits, zoologists are agreed; and we have above endeavoured to describe the peculiar apparatus with which they are furnished. Where the "aculeated tongue" fitted for insertion "into the vein of a sleeping person" is to be found among the known bats, we are ignorant. The rough tongue of the genus *Pteropus* has been supposed to have been employed for abrading the skin, to enable the animal to suck the part abraded, but zoologists are now agreed that the supposition is groundless. It is more than probable that the celebrated Vampire superstition and the blood-sucking qualities attributed to the Bat have some connection with each other.

Piso describes the bodies of his Bats (Andira-guaca) as being as large as European pigeons.

Madateus, Leach. Characterised by four incisors in each jaw; the two intermediate upper ones are longer than the lateral; they are bifid; the lower incisors are equal, simple, and pointed. Four molar teeth in the upper and five in the lower jaw on each side. Two nasal leaves. No tail. Lips furnished with soft fringed and compressed papillæ. Tongue bifid at the point.

M. Lewisii. Nasal leaf suddenly pointed; ears moderate and rounded. Fur blackish. Interfemoral membrane notched. Expansion 16 inches. Locality, Jamaica.

Glossophaga. Four incisors in each jaw; canines moderately strong. Tongue very long, extensile, and terminated by a sort of sucker. Nose surmounted by a crest in form of a pike-head. Tail none, or variable in length. Interfemoral membrane very small, hardly any.

Incisors $\frac{4}{4}$; canines, $\frac{1-1}{1-1}$; molars, $\frac{3-3}{3-3}=24$.

Locality, entirely American. The extensile tongue, says Lesson, enables the species to suck the blood of animals.

G. soricina of Geoffroy, *Vespertilio soricinus* of Pallas and Gmelin. Interfemoral membrane comparatively large. No tail. Locality, Surinam and Cayenne.

Rhinopoma, Geoff. Two incisors in the upper jaw, four in the lower. Nose long, conical, cut square as it were at the end, and surmounted with a small leaf. Nostrils straight, transversal, and operculated. Ears large, earlet (oreillon) external. Tail long, enveloped at its base in the interfemoral membrane, which is cut as it were square, and free at the extremity.

Incisors, $\frac{2}{4}$; canines, $\frac{1-1}{1-1}$; molars, $\frac{4-4}{5-5}=28$.

There are two species only; one African, the other American.

R. microphylla. This is Belon's Chauve-Souris d'Egypte. The fur is ash-coloured, and the tail very long and slender. It is the species that abounds in the long and dreary galleries of the Egyptian Pyramids.

Artibeus, Leach. Four incisors in each jaw, of which the upper ones are bifid and the lower ones truncated. Two canines above and the same number below; the upper ones have an internal border at their base. Four molars above and five below on each side. Two nasal leaflets; one horizontal, the other vertical. No tail.

A. Jamaicensis, the only species known. Brown above, grayish below. Flying membranes, and ears brownish. The lips are surrounded with a regular series of warts, and the mouth is provided internally with a narrow, fimbriated, cribriform membrane. Expansion about 1 foot, 3 inches. Length from the muzzle to the extremity of the interfemoral membrane, 4 inches, 10 lines. Dr. Horsfield calls it *Phyllostoma Jamaicense*, and says that in many particulars it agrees with *Phyllostoma planirostrum* of Spix, though it is clearly distinguishable from it.

Monophyllus, Leach. Four unequal incisors in the upper jaw, of which the two middle ones are longer than the lateral, and bifid; none in the lower jaw; two canines in each jaw. Five molars above and six below on each side. A single straight leaf upon the nose. Tail short.

M. Redmani. Brown above, grayish below. Ears rounded. Nose-leaf, which is sharp, covered with small white hairs. Membranes brown. Locality, Jamaica.

2. Sub-Family, *Rhinolophina.*

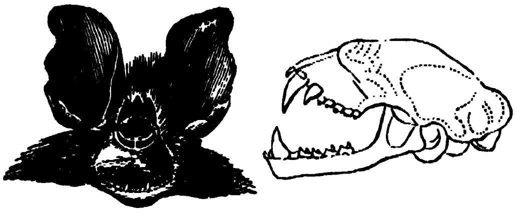
Nasal leaf complicated, membranous. Index with a single phalanx. Wings largely developed. Females with pectoral teats often accompanied by pubic warts simulating mamillæ.

Rhinolophus, Geoff. Nose at the bottom of a cavity bordered by a wide crest of a horseshoe shape, and surmounted by a leaf. Ears moderate, lateral, without an earlet (oreillon). Tail long, entirely enveloped by the interfemoral membrane, which is very much developed.

Incisors, $\frac{2}{4}$; canines, $\frac{1-1}{1-1}$; molars, $\frac{5-5}{6-6}=32$.

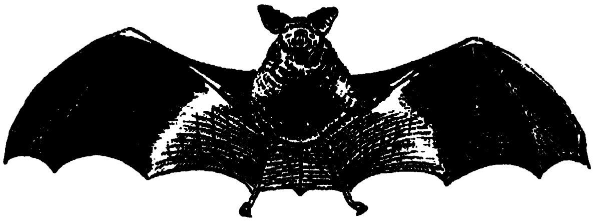
There are several species.

R. tridens (*Asellia tridens*, Gray) is a native of Egypt.



Head and skull of *Rinolophus tridens*.

R. nobilis is a rare and fine Javanese species: it is the Kêbblêk of the natives. It was described by Dr. Horsfield, who observes that it belongs to the second section of the genus. The nasal apparatus consists of a broad membrane stretching transversely across the nose in form of a shelf; the sides are bounded by several parallel folds, and inferiorly it constitutes a semicircular envelope, which has a short obtusely-rounded point in the middle. Colour above, pure brown; beneath, brown variegated with gray. Fur remarkably long and silky, and supplied with a most delicate down at the base, so as to be throughout very soft to the touch. Body 4 inches in length. Expansion 19¼ inches.

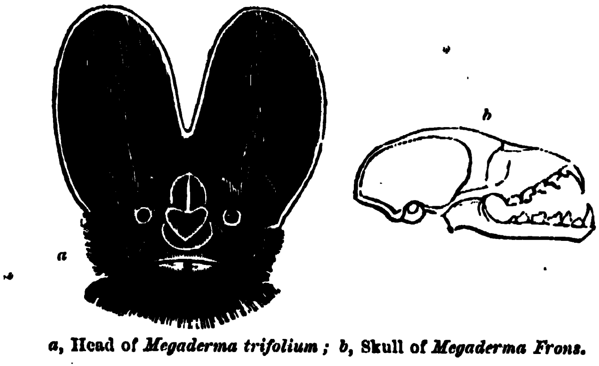


Rhinolophus nobilis.

Megaderma, Geoff. Ears very much developed, and brought forward on the head. Earlet internal, wide. Three nasal crests, one vertical, one horizontal, and one inferior of a horseshoe shape. No tail. Interfemoral membrane cut square.

Incisors, $\frac{0}{4}$; canines, $\frac{1-1}{1-1}$; molars, $\frac{4-4}{5-5}=26$.

M. trifolium. Locality, Java, where it is the Lovo of the natives.

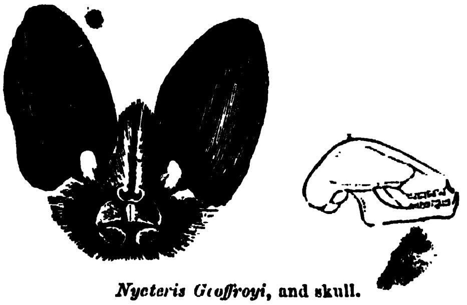


a, Head of *Megaderma trifolium*; *b*, Skull of *Megaderma Frons*.

Nycteris, Geoff. A very deep longitudinal sillon upon the chanfrein. Nostrils covered by a cartilaginous moveable operculum. Ears large, united at their base. Earlet external. Interfemoral membrane very large, comprehending the tail, the last vertebra of which is terminated by a bifurcated cartilage.

Incisors, $\frac{4}{6}$; canines, $\frac{1-1}{1-1}$; molars, $\frac{4-4}{5-5}=32$.

N. Geoffroyi. Fur, gray-brown above; brighter below. Ears very large. A well-developed wart placed upon the lower lip, between two bourrelets, having the form of a V. Locality, the Thebaïd and Senegal.



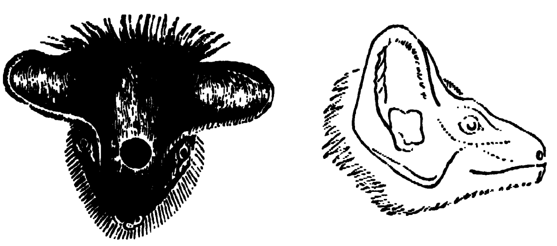
Nycteris Geoffroyi, and skull.

Taphozous, Geoff. Chanfrein with a sillon. Upper lip thick. Ears moderate and wide apart. Tail fine towards its point, beyond the interfemoral membrane, which is large, prolonged, and angular at its external border.

$$\text{Incisors, } \frac{0}{4}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{5-5}{5-5}=28.$$

There are several species.

T. Mauritianus. Fur, chestnut above, ruddy below. Earlet terminated by a sinuous border. Locality, Mauritius.



Taphozous Mauritianus, and profile of the same.

Mormops, Leach. Four upper unequal incisors, of which the intermediate ones are widely notched, and four below which are equal and trifid; two canines in each jaw, the upper ones twice the length of those below, almost compressed and canaliculated before; five molars above and six below on each side. A single nasal leaf united to the ears, which are very complicated.

M. Blainvillii, the only species; and it is remarkable for the extreme elevation of its front; the excavation of its chanfrein; the lobated crenellated form of its upper lip, and the division of the lower one into three membranous lobes; the existence on the tongue of papillæ, of which the anterior are bifid and the posterior multifid; the folding of the nasal leaf, and the division of the upper border of its ears into two lobes. Locality, Jamaica.

Nyctophilus, Leach. Two upper, elongated, conical, pointed incisors; six lower ones, equal and trifid, with rounded lobes; two canines above and two below, the lower ones having a small point at the back part of their base. Four molars on each side of the jaws, with crowns furnished with pointed tubercles. Two nasal leaves, of which the posterior is the largest. Tail projecting a little beyond the interfemoral membrane.

N. Geoffroyi, the only species known. Fur, yellowish above. Belly, breast, and throat dirty white. Ears large. Membranes brownish-black.

§ 2. *Anistiophori*, Spix.

Bats without any nasal appendage.

3. Sub-Family, *Vespertilionina.*

Molar teeth with pointed tubercles. Wings wide and extended A single phalanx to the forefinger (index). Head elongated. The lips simple. Tongue short. Tail long.

Vespertilio, Linn., Geoff. Upper incisors four, sometimes two. Lower incisors six. Muzzle very simple. Ears separated, but sometimes united at their base. Earlet internal. Tail long, entirely enveloped in the interfemoral membrane. Cheek pouches.

$$\text{Incisors, } \frac{4}{6}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{4-4}{5-5}=32.$$

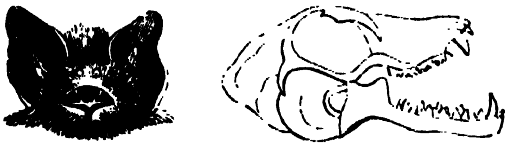
Lesson observes, that many *Vespertiliones* have but two incisors. The species of the genus are many in number, and their geographical distribution is very wide.

α. European Species.

V. murinus, Linnæus. This is the Flitter-Mouse, Flutter-Mouse, and Rear-Mouse, of the English; La Chauve-Souris of Buffon, and, according to Pennant, the Ystlum of the Welsh; the Nattola, Notula, Sporteglione, Vispistrello, and Vilpistrello, of the Italians; Murciegalo and Morciegalo of the Spaniards; Morcego of the Portuguese; Speckmaus and Fledermaus of the Germans; Vledermuys of the Dutch; Laderlap and Fladermus of the Swedes; and Flagermaus and Aftenbakke of the Danes.

The ears are oval, of the length of the head; the earlets falciform. The fur of the adults is ruddy-brown above, whitish-gray below; that of young individuals is gray-ash.

This species is common in Europe. It has been supposed to exist in Asia, and even in Australia. Its haunts are caves, ruined buildings, church-towers, the roofs of houses or churches, and hollow trees, where it hybernates during the whole winter, snugly wrapped up in the wing membranes, and suspended by the hind feet. We have given the skeleton of this species, and below will be found a head and skull of *V. Pipistrellus*, another European species.



Head and skull of *Vespertilio Pipistrellus*.

β. African Species.

V. nigrita. Adanson discovered this species at Senegal. The ears are oval, triangular, very short, one-third of the length of the head. Earlet long, and terminating in a point. Fur yellowish-brown above, and yellowish-ash below.

γ. Asiatic Species.

V. pictus. The ears are shorter than the head, oval, wider than they are high. Earlet oval-shaped. The fur is reddish, passing into bright yellow upon the back, and of a tarnished yellow on the belly. Citron-coloured rays mark the course of the fingers in the wings, which are chestnut-brown. Locality, Ceylon.

δ. American Species.

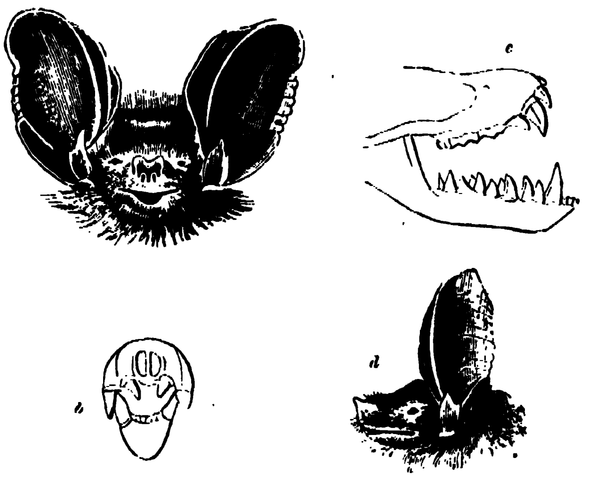
V. Naso. This species, remarkable for the length of its nose, was first described by the Prince de Neuwied. The nasal organ is elongated in a straight line above the upper jaw, almost like a proboscis. The ears are small, and very much pointed. The fur is grayish-brown above and yellowish-gray below. Locality, Brazil, in trees.

Plecotus, Geoff. This genus in many of its characters agrees with *Vespertilio*, but the ears are very much developed, being larger than the head.

$$\text{Incisors, } \frac{4}{6}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{5-5}{6-6}=36.$$

There are several species, and the form occurs in all the four quarters of the globe.

P. Timoriensis. This species was discovered by Péron and Lesueur in the island of Timor, one of the Moluccas. The ears are ample, united at their base by a small membrane. The fur is blackish-brown above, and ash-brown below.



Plecotus Timoriensis.
b, front view of the teeth, &c.; *c*, profile of the skull; *d*, profile of the head.

The genera *Atalapha*, *Hypexodon*, and *Nycticeus* of Rafinesque, are considered doubtful by Lesson and others.

Myopteris, Geoff. The chanfrein is united and simple. The ears are large, insulated, and lateral, with an internal earlet. Tail long, half enveloped in the interfemoral membrane. Muzzle short and large.

$$\text{Incisors, } \frac{2}{2}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{4-4}{5-5}=26.$$

M. Daubentonii, Geoff.; Le Rat Volant (Flying Rat) of Daubenton. The locality of this species is unknown. The upper part of the head and body is brown; beneath, the colour is dirty white, with a slight tinge of yellow.

4. Sub-Family, *Noctilionina.*

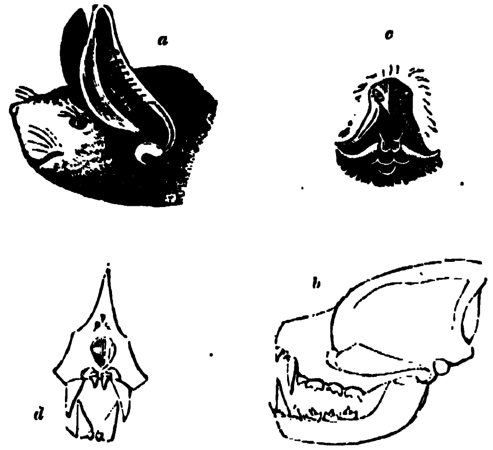
Molars tubercular. Wings long and straight. Two phalanges to the forefinger (index). Head short and obtuse. Lips very large.

Tail recurved. The females often furnished with lateral pouches for the reception of the young in nursing.

Noctilio, Geoff. Canines very strong. Muzzle short and swollen, and divided and studded with fleshy tubercles or warts. Nose simple, and losing itself in the lips. Ears small and lateral. Interfemoral membrane very much developed. Tail enveloped at its base.

$$\text{Incisors, } \frac{4}{2}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{4-4}{5-5} = 28.$$

N. Leporinus. Size of a rat. Fur of a uniform reddish-yellow. This is the *Vespertilio Leporinus* of Gmelin; *Noctilio unicolor* of Geoffroy. Localities, Brazil, Peru, and Paraguay.



Noctilio Leporinus.

a, Profile of head; *b*, profile of skull; *c*, front view of muzzle; *d*, front view of teeth, &c.

Dysopes, Illiger. M. Temminck is of opinion that *Molossus*, *Nyctinomus*, and *Cheiromeles* are identical with *Dysopes*. The following is the character of the teeth, according to F. Cuvier: two incisors above and four below; two canines in each jaw; four molars on each side of the upper jaw; that is to say, two false and two normal; ten molars in the lower jaw, namely, four false and six true. Type, *D. Moops*. We proceed to give the definition of *Molossus*, *Cheiromeles*, and *Nyctinomus*, for the assistance of the student.

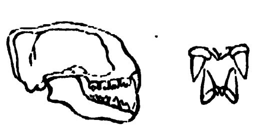
Molossus. Head short; muzzle swollen. Ears large; earlet external. Interfemoral membrane straight, with a square termination. Tail long, enveloped at its base, and most frequently free at its extremity.

$$\text{Incisors, } \frac{2}{2}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{5-5}{5-5} = 28.$$

The geographical distribution of this form is wide: Africa, Asia, and South America possess it: but the species, which are numerous, occur principally in the two last-mentioned localities.

M. obscurus, *M. fumarius* of Spix, *Dysopes obscurus* of Temminck. Size of the Barbastelle of Europe. Fur composed of hair of two colours, blackish-brown above, and ash-brown below. Whiskers at the border of the lips. Length about 3 inches, 3 lines. Expansion 9 inches. Localities, Brazil and Guyana.

Head of *Molossus obscurus*.



Skull and front teeth.

Cheiromeles, Horsfield. Two incisors above and two below; the upper ones large, approximate, semiconical, and acute, the lower very small and simple. Muzzle conical, sulcated, and with setiferous glandules. Ears distant, patent, with a short, semicordate, obtuse operculum. Axillary pouch ample; but the hind foot, according to Dr. Horsfield, constitutes the chief distinguishing character. The hind foot, or rather hand, "consists of four fingers, which have the same disposition and structure as in other animals of this family, and of a distinct thumb, essentially agreeing with this member in many *Quadrumana*, and in several animals of the *Rodentia* and *Marsupialia*. It is a complete antagonist to the fingers, enables the animal to take hold of objects, and thus constitutes a perfect hand."

C. torquatus, Horsfield, 'Researches in Java;' *Molossus Cheiropus*, Auct.; *Dysopes Cheiropus*, Temminck. Length, 5¼ inches. Expansion nearly 2 feet. Localities, Siam and Western Asia.

Nyctinomus, Geoff. Nose flat, losing itself in the lips, which are deeply slit and wrinkled. Ears large, and hanging with an external earlet. Interfemoral membrane moderate and angular. Tail long, and nearly half of it enveloped.

$$\text{Incisors, } \frac{2}{4}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{5-5}{5-5} = 30.$$

Localities. This form occurs in Africa, Asia, and South America.

N. Ægyptiacus, Geoff.; *Dysopes Geoffroyi*, Temminck. Reddish above and brown below. Tail slender. Interfemoral membrane enveloping only half of the tail. Locality, ruins and subterraneous places in Egypt.

Dinops, Savi. Ears united and extended on the front. Lips pendent and plaited. Tail enveloped for half its length in the interfemoral membrane.

$$\text{Incisors, } \frac{2}{6}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{5-5}{5-5} = 32.$$

D. Cestonii, Savi. Fur thick and soft, gray-brown, tending slightly to yellowish, but a little browner on the back. Wings black-brown. Muzzle, lips, and ears black, the latter large, rounded, and a little notched on their external border. Tail long, of a brown-black. Locality, the environs of Pisa, where Savi discovered it.

Stenoderma, Geoff. Nose simple. Ears small, lateral, and isolated; earlet internal. Interfemoral membrane rudimentary, and bordering the legs. No tail.

$$\text{Incisors, } \frac{4}{4}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{4-4}{4-4} = 28.$$

But it should be remembered that Cuvier only allows of two incisors in the upper jaw, instead of four, the number given by Geoffroy.

S. rufa. Fur uniform, chestnut-red. Ears moderate, oval, and a little notched on their external border.

Celæno, Leach. Two upper incisors pointed and simple; four lower ones contiguous and cylindrical. Two canines above and below, the upper ones largest. Four molars on each side of the jaws, the first pointed and simple, and the last three with their crowns beset with points. Third and fourth finger with three phalanges, the fifth or external with two only. Interfemoral membrane prolonged a little below the toes of the hind feet. Ears separated; earlets simple. No tail.

C. Brooksiana. Back ferruginous; belly and shoulders yellowish-ferruginous. Ears pointed, with the anterior border rounded and the posterior one straight. Membranes black.

Ællo, Leach. Two upper incisors large, compressed, bifid, and with rounded lobes. Two lower equal, trifid, with rounded lobes. Two upper canines, long, very sharp, with a small projecting point before and behind their base; the two lower smaller and less pointed. Four upper molars on each, the two first pointed and triangular, the second largest, the third bifid, and the fourth trifid externally. Third finger of the wings with four phalanges, fourth and fifth with three. Interfemoral membrane straight. Ears contiguous, short, very large; no earlet. Tail not exceeding the membrane.

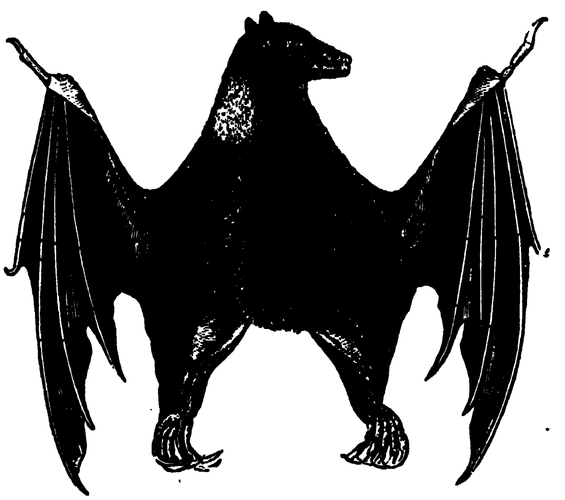
A. Cuvieri. Colour ferruginous-Isabella. Wings obscure brown. Ears truncated, as it were, at the end.

Scotophilus, Leach. Four upper incisors unequal, pointed, the intermediate ones being largest and simple, and the lateral ones bifid with equal lobes: six lower incisors indistinctly trifid. Two canines above and below, the upper ones with a small point behind their base, and the corner ones with a similar one in front. Four molars with crowns armed with points. Fourth and fifth fingers of the wings with three phalanges.

S. Kuhlii. Fur ferruginous. Ears, nose, and wings brown.

5. Sub-Family, *Pteropina*.

We now come to a numerous and widely distributed family containing some of the largest forms of the *Vespertilionidæ*, and subsisting principally on vegetables and fruits. It is not improbable that the fabulous Harpy may have had its origin in some of these enormous bats with their well-developed pectoral mammæ.



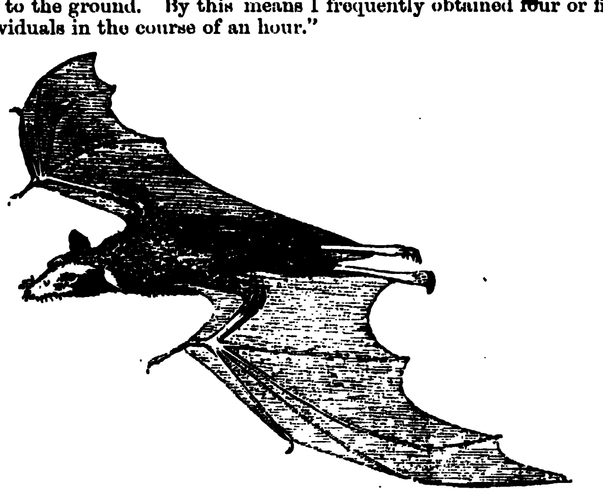
Pteropus Dussumieri.

Molar teeth tuberculated and grooved longitudinally. Wings rounded. Interfemoral membrane and tail often wanting. Index with three phalanges. Head long and hairy. Females for the most part with nursing pouches.

Pteropus, Brisson (Roussettes of the French). A small nail on the index wing-finger. Head conical. Ears short. Tail absent, or rudimentary. Interfemoral membrane very little developed.

a. Tailless.

P. Javanicus. Upper part of the neck smoky red, rest of the fur blackish, some white hairs mingled with the black ones of the back. Expansion 5 feet. This is the Kalong of the Javanese, which, according to Dr. Horsfield, is extremely abundant in the lower parts of Java, and uniformly lives in society. The more elevated districts are not visited by it. "Numerous individuals," continues the Doctor, "select a large tree for their resort, and suspending themselves with the claws of their posterior extremities to the naked branches, often in companies of several hundreds, afford to a stranger a very singular spectacle. A species of *Ficus*, in habit resembling the *F. religiosa* of India, which is often found near the villages of the natives, affords them a very favourite retreat, and the extended branches of one of those are sometimes covered by them. They pass the greater portion of the day in sleep, hanging motionless: ranged in succession, with the head downwards, the membrane contracted about the body, and often in close contact, they have little resemblance to living beings, and by a person not accustomed to their economy are readily mistaken for a part of the tree, or for a fruit of uncommon size suspended from its branches. In general these societies preserve a perfect silence during the day: but if they are disturbed, or if a contention arises among them, they emit sharp piercing shrieks, and their awkward attempts to extricate themselves when oppressed by the light of the sun, exhibit a ludicrous spectacle. In consequence of the sharpness of their claws, their attachment is so strong, that they cannot readily leave their hold without the assistance of the expanded membrane: and if suddenly killed in the natural attitude during the day, they continue suspended after death. It is necessary therefore to oblige them to take wing by alarming them, if it be desired to obtain them during the day. Soon after sunset they gradually quit their hold, and pursue their nocturnal flight in quest of food. They direct their course by an unerring instinct to the forests, villages, and plantations, occasioning incalculable mischief, attacking and devouring indiscriminately every kind of fruit, from the abundant and useful cocoa-nut which surrounds the dwelling of the meanest peasantry, to the rare and most delicate productions which are cultivated with care by princes and chiefs of distinction. By the latter, as well as by the European colonists, various methods are employed to protect the orchards and gardens. Delicate fruits, such as mangoes, jambus, lansas, &c., as they approach to maturity, are ingeniously secured by means of a loose net or basket, skilfully constructed of split bamboo. Without this precaution, little valuable fruit would escape the ravages of the Kalong. There are few situations in the lower parts of Java in which this night wanderer is not constantly observed: as soon as the light of the sun has retired one animal is seen to follow the other at a small but irregular distance, and this succession continues uninterrupted till darkness obstructs the view. The flight of the Kalong is slow and steady, pursued in a straight line, and capable of long continuance. The chase of the Kalong forms occasionally an amusement of the colonists and inhabitants during the moonlight nights, which in the latitude of Java are uncommonly serene. He is watched in his descent to the fruit-trees, and a discharge of small shot readily brings him to the ground. By this means I frequently obtained four or five individuals in the course of an hour."



Pteropus Javanicus.

β. With Tails.

P. stramineus. Fur reddish-yellow; tail very short. Expansion two feet. Brought from Timor by Péron and Lesueur.

γ. With Wings on the Back.

Cephalotes, Geoff. A small nail on the index in one species. Head conical; ears short; tail but little apparent. Interfemoral membrane notched. Flank-membrane springing from the mesial line of the back.

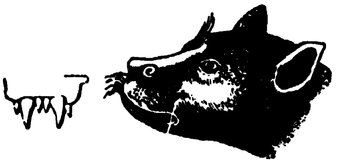
$$\text{Incisors, } \frac{4}{6};\ \text{canines, } \frac{1-1}{1-1};\ \text{molars, } \frac{5-5}{4-4}=32.$$

C. Peronii. Fur brown or red, and very short. No nail on the index. Wings springing from the middle of the back. Expansion two feet. Locality, Timor. N.B. Temminck thinks that the *P. palliatus* of Geoffroy is the young of this species.

Harpya, Illiger. Differing from *Cephalotes* in the want of lower incisors and of the last small molars in both jaws. Geoffroy thinks that the difference between the system of dentition in *Harpya* and *Cephalotes Peronii* is attributable to age only.

$$\text{Incisors, } \frac{2}{0};\ \text{canines, } \frac{1-1}{1-1};\ \text{molars, } \frac{4-4}{5-5}=24.$$

H. Pallasii (*Cephalotes Pallasii*, Geoff.). Fur consisting of scanty and soft hairs, grayish-ash above, pale white below. A nail on the index. Expansion 1 foot 11 inches. Locality, the Moluccas.



Head of *Harpya Pallasii.*

Cynopterus, F. Cuvier. Four incisors and two rudimentary false molars in each jaw, like the *Pteropi*, but they entirely want the last molars. The jaws are abbreviated, and the heads much resemble those of *Cephalotes.*

Macroglossa, F. Cuvier. A genus approaching very closely to *Pteropus* and formed by F. Cuvier for the Lowo-assu of the Javanese, *P. minimus* of Geoffroy, *P. rostratus* of Horsfield. Its character depends upon the extreme length of the head, the absence of false molars, the great development of the posterior molar and the extensile tongue.

$$\text{Incisors, } \frac{4}{4};\ \text{canines, } \frac{1-1}{1-1};\ \text{molars, } \frac{5-5}{6-6}=34.$$

M. Horsfieldii (*Pteropus rostratus*, Horsfield). Temminck is of opinion that *M. Kiodotes*, *P. minimus*, Geoff., and *M. Horsfieldii* are identical.

δ. Wings placed extremely backwards.

Epomophorus (Gray). *E. Whitii* (*Pteropus Epomophorus*, Bennett). Pale brown, the colour being paler posteriorly; belly white; humeral brush (or epaulette) white and large. Total length, six inches three quarters; length of the head, two inches and a quarter. Expansion 12 inches.

The following is the arrangement of the species of this order of which there are specimens in the British Museum, as given in the list of the *Mammalia* by Dr. J. E. Gray:—

Vespertilionidæ.

A. Istiophori.

a. Phyllostomina.

1. *Rhinopoma Hardwickii*, the Indian Rhinopome.
2. *R. microphylla*, the Egyptian Rhinopome. Egypt.
3. *Sturnira Spectrum*, the Sturnira. Brazils.
4. *Arctibeus Jamaicensis*, the Jamaica Arctibeus. Jamaica and Brazils.
5. *A. fimbriatus*, the Fringe-Lipped Arctibeus. Brazils.
6. *A. verrucatus*, the Warty-Chinned Arctibeus. South America.
7. *A. falcatus*, Sickle-Arctibeus. Cuba.
8. *Vampyrus Spectrum*, the Pale Vampire. Jamaica.
9. *Phyllostoma hastatum*, the Javeline Phyllostome. Brazils.
10. *P. fuliginosum*, the Sooty Phyllostome. South America.
11. *P. Childreni*, Children's Phyllostome. South America.
12. *P. soricinum*, the Soricine Phyllostome. Jamaica, West Indies.
13. *P. Bennettii*, Bennett's Phyllostome. South America.
14. *P. lanceolatum*, Long-Leaved Phyllostome. South America.
15. *P. elongatum*, Elongated Phyllostome. Brazils.
16. *Brachyphylla Cavernarum*, the Cavern-Bat. St. Vincent's, West Indies; Cuba.
17. *Phyllophora megalotis*, Large-Eared Phyllophore. Brazils.
18. *P. nigra*, Black Phyllophore. Brazils.
19. *P. amplexicaudata*, West-Indian Phyllophore. West Indies, Jamaica.
20. *Glossophaga Soricina*, the Soricine Bloodsucker. Jamaica, West Indies.
21. *Monophyllus Redmani*, Redman's Leaf-Nosed Bat. Jamaica.
22. *Anoura Geoffroyi*, Geoffroy's Tailless Bat. Brazils.
23. *Megaderma Lyra*, Lyre-Nosed Broad-Winged Bat. Java; India, Madras and Bengal.
24. *M. Spasma*, the Cordate Bat. Java and Singapore.
25. *Lavia frons*, the African Leaf-Bat. West Africa, Gambia.

b. Rhinolophina.

26. *Ariteus flavescens*, the Yellowish Ariteus.

27. *Rhinolophus Hipposideros*, the Smaller Horseshoe-Bat. Devonshire.

28. *R. ferrum-equinum*, the Larger Horseshoe-Bat. England and Turin.

29. *R. megaphyllus*, the Large-Leaved Horseshoe-Bat. Australia.

30. *R. morio*, the Black Horseshoe-Bat. Singapore.

31. *R. tragatus*, Nepaul Horseshoe-Bat. Nepaul.

32. *R. Capensis*, Cape Horseshoe-Bat. Cape of Good Hope.

33. *R. clivosus*, Short-Faced Horseshoe-Bat. North Africa.

34. *Hipposideros fulvus*, Foxy Horseshoe-Bat. India, Madras.

35. *H. murinus*, Mouse-Coloured Horseshoe-Bat. India, Madras.

36. *H. bicolor*, *Rhinolophus bicolor*, Two-Coloured Horseshoe-Bat. Java.

37. *H. apiculatus*, Apicillated Horseshoe-Bat. India, Madras.

38. *H. larvatus*, Masked Horseshoe-Bat. Java.

39. *H. penicillatus*, Pencilled Horseshoe-Bat. Madras.

40. *H. vulgaris*, Javanese Horseshoe-Bat. Java.

41. *H. nobilis*, Noble Horseshoe-Bat. Java.

42. *H. armiger*, Hodgson's Horseshoe-Bat. Nepaul.

43. *Asellia tridens*, the Three-Toothed Asellia. Egypt.

B. Anistiophori.

c. Vespertilionidæ.

44. *Nycteris Thebaica*, Egyptian Nycteris. Egypt.

45. *N. Damarensis*, Damara Nycteris. South Africa, Damara country.

46. *N. Poensis*, Fernando Po Nycteris. Africa, Fernando Po.

47. *Petalia Javanica*, Kuhl's Petalia. Java.

48. *Nyctophilus Geoffroyi*, the Australian Nyctophile. Australia.

49. *Barbastellus communis*, the Barbastelle. England.

50. *Plecotus communis*, Common Long-Eared Bat. England, London.

51. *P. Christii*, Egyptian Long-Eared Bat. North Africa, Egypt.

52. *Romicia calcarata*, the Long-Spurred Romicia.

53. *Vespertilio mystacinus*, the Whiskered Bat. Devonshire and Cambridgeshire.

54. *V. Daubentonii*, Daubenton's Bat. Scotland, Aberdeen.

55. *V. Caroli*, Prince Charles's Bat. North America.

56. *V. muricola*, the Wall-Bat. Nepaul.

57. *Trilotitus Blepotis*, the Blepote. Timor.

58. *T. Horsfieldii*, the Lowo-Manir. Java; India.

59. *Myotis murinus*, the Large-Eared Bat. Hamburg and England.

60. *M. Bechsteinii*, Bechstein's Bat. New Forest, Hampshire.

61. *M. Nattereri*, Natterer's Bat. England.

62. *Kerivoula picta*, the Kerivoula. Java.

63. *K. formosa*, the Nepaul Kerivoula. Nepaul.

64. *K. Sykesii*, Sykes's Kerivoula. India, Calcutta.

65. *K. trilatitoides*, the Javanese Kerivoula. Java.

66. *K. Hardwickii*, Hardwicke's Kerivoula. Java.

67. *K. Poensis*, the Fernando Po Kerivoula. Fernando Po.

68. *K. grisea*, the Gray Kerivoula.

69. *K. Brasilensis*, the Brazilian Kerivoula. Brazils.

70. *Natalus stramineus*, the Natale. America.

71. *Scotophilus Serotinus*, the Serotine. England.

72. *S. discolor*, Parti-Coloured Bat. England.

73. *S. Leisleri*, the Hairy-Armed Bat. England.

74. *S. murinus*, the Bat. England; North of Scotland; Hamburg; and Madeira.

75. *S. fuliginosus*, the Sooty Scotophile. Nepaul.

76. *S. Hodgsonii*, the Indian Bat. India, Calcutta.

77. *S. lobatus*, the Lobed Scotophile. India.

78. *S. Maderaspatanus*, the Madras Bat. Madras.

79. *S. morio*, the Australian Bat. Van Diemen's Land, Australia.

80. *S. Gouldii*, Gould's Scotophile. Van Diemen's Land.

81. *S. pumilus*, the Dwarf Bat. Australia.

82. *S. Greyii*, Captain Grey's Bat. Australia.

83. *S. Cubensis*, the Cuba Bat. Cuba.

84. *S. MacLeayii*, MacLeay's Bat. Cuba.

85. *S. Bellii*, Bell's Bat. West Indies.

86. *S. Greenii*, Green's Bat. North America.

87. *S. Temminckii*, Temminck's Noctule. Calcutta and Java.

88. *S. falcatus*, the Falcated Noctule. India.

89. *S. Leachii*, Leach's Noctule. India.

90. *S. fulvus*, the Foxy Noctule. Java and Madras.

91. *Noctulinia altivolans*, the Noctule. England.

92. *N. Malaccensis*, the Singapore Noctule. Singapore.

93. *N. labiata*, Large-Lipped Noctule. Nepaul.

94. *Lasiurus rufus*, the Red Hairy-Tailed Bat. America.

95. *L. pruinosus*, the Powdered Hairy-Tailed Bat. North America.

96. *Scotophilus Capensis*, the Cape Bat. Cape of Good Hope.

97. *Murina suillus*, the Pig-Nosed Bat. India.

d. Noctilionina.

98. *Taphozous perforatus*, the African Taphozous. Africa and Mauritius.

99. *T. longimanus*, the Long-Armed Taphozous. India, Calcutta.

100. *T. nudiventer*, the Naked-Bellied Taphozous. Africa, Nubia.

101. *T. melanopogon*, the Black-Bearded Taphozous. Caves of Kenneri, Hindustan.

102. *T. saccolaimus*, the Javanese Taphozous. Java.

103. *Noctilio Americanus*, the Bull-Dog Bat. Para.

104. *N. mastivus*, the Striped Bull-Dog Bat. Brazils and Central America.

105. *Mosia nigrescens*, the Mosia. South America.

106. *Mystacina tuberculata*, the Mystacine. New Zealand.

107. *Centurio senex*, the Wrinkled-Faced Epaulet-Bat. Amboyna.

108. *Chenolycteris MacLeayii*, MacLeay's Fringe-Nosed Bat. Cuba.

109. *Mormops Blainvillii*, the Mormops. Cuba and South America.

110. *Nyctinomus plicatus*, the Groove-Cheeked Bat. Java and Bengal.

111. *N. Rüppellii*, Rüppell's Groove-Cheeked Bat. Fernando Po and Singapore.

112. *N. pumilus*, the Smaller Groove-Cheeked Bat. Egypt.

113. *N. murinus*, the Murine Groove-Cheeked Bat. Jamaica.

114. *N. macrotis*, the Large-Eared Groove-Cheeked Bat. Cuba.

115. *Molossus velox*, the Swift-Flying Thick-Lipped Bat. Brazils, and St. Lucia, West Indies.

116. *M. fuliginosus*, the Sooty Thick-Lipped Bat. Bermuda, Jamaica, and Portobello.

117. *M. rufus*, the Reddish Thick-Lipped Bat. Brazils.

118. *M. tropidorhynchus*, the Ridge-Nosed Thick-Lipped Bat. Cuba.

119. *M. Braziliensis*, the Brazilian Thick-Lipped Bat. Brazils.

120. *M. Norfolcensis*, the Norfolk Island Thick-Lipped Bat. Norfolk Island.

121. *Diclidurus Freyreisii*, the Diclidure. Pueblo Nuevo, Tropical America.

e. Pteropina.

122. *Pteropus poliocephalus*, Gray-Headed Kalong. Australia.

123. *P. Edwardsii*, the Wurba-Gool. India, Nepaul, and Molucca.

124. *P. edulis*, the Kalong. Sumatra.

125. *P. funereus*, Red-Naped Kalong. Australia, Port Essington.

126. *P. pselaphon*, Hairy-Footed Kalong. Island of Bonin (Loo-Choos).

127. *P. rubricollis*, the Roussette. Cape of Good Hope.

128. *Xantharpyia amplexicaudata*, the Xantharpye. Amboyna.

129. *X. Ægyptiaca*, Egyptian Xantharpye. North Africa, Egypt.

130. *X. straminea*, the Pale Xantharpye. Africa.

131. *Epomophorus Whitii*, the Shoulder-Knot Bat. West Africa, Gambia.

132. *Cynopterus marginatus*, the Margin-Eared Cynoptere. India, Java, and Nepaul.

133. *C. Horsfieldii*, Horsfield's Cynoptere. Java and India.

134. *C. brevicaudatus*, the Short-Tailed Cynoptere.

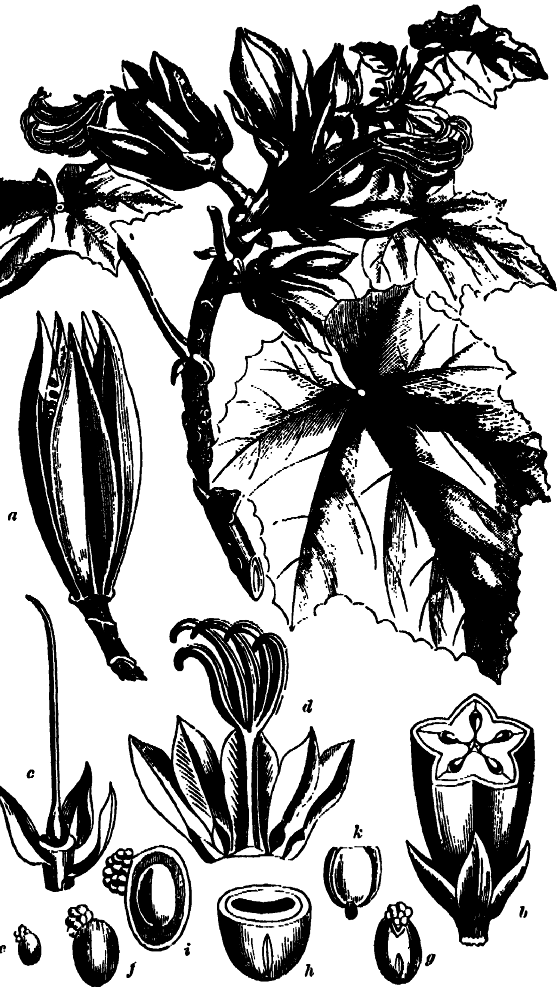
135. *C. affinis*, the Indian Cynoptere. Himalaya.

136. *Macroglossus minimus*, the Kiodote. Java.

Fossil Cheiroptera.

Cuvier described the skeleton of a species of bat allied to the Serotine, which was petrified and imbedded in a block of the Eocene Gypsum at Montmartre, Paris. Some fossil teeth resembling those of a Cheiropterous animal have been found in the Eocene Sand at Kyson near Woodbridge in Suffolk. More numerous remains of this family have been met with in England in the limestone caverns containing the fossil bones of extinct bears, hyænas, and other animals. Professor Owen says of these remains that he has "failed to detect in the more complete skulls and skeletons from cave-localities any character by which they could be distinctly referred to unknown species of bats, or to such as do not now exist in England; and after much pains bestowed on the less complete and more abundant fragmentary and detached parts of the enduring framework of the *Cheiroptera* I have been seldom able—partly indeed from the still imperfect state of the osteology of this order—to arrive at any sound specific determinations." One of the most complete examples of the skeleton of a bat from a crevice of a bone-cave in the Mendip Hills Professor Owen refers to *Vespertilio noctula.* Remains of a bat from the bone-cave called Kent's Hole, near Torquay, Devon, are preserved in the British Museum; and from an examination of these Professor Owen concludes that they belong to the *Rhinolophus ferrum-equinum*, the Great Horseshoe-Bat, which is not now a native of these islands. Other Cheiropterous remains have been found in the bone-caves of the continent of Europe.

CHEIROSTE'MON, a genus of plants belonging to the natural order *Sterculiaceæ.* *C. platanoides*, a most singular plant, is commonly called the Hand-Tree, in consequence of its stamens being so arranged as to present an appearance somewhat similar to that of a human hand. It is a lofty tree, with the habit of a plane, and a trunk about as thick as a man's body. Its head divides into a number of close horizontal branches, which are of a brownish colour towards their extremities in consequence of the number of short fawn-coloured hairs that beset them. The leaves are heart-shaped, slightly 7-lobed, six or eight inches long, and a little toothed; they are of a rich deep green on the upper side, and are covered with fawn-coloured hairs on the under side. The flowers are of a bright red, and appear at the end of the branches; they consist of three external lanceolate brownish bracts, and a bell-shaped fleshy angular calyx, about an inch and a half deep, bright red inside, covered externally with a russet down; it is deeply divided into five lobes, and is marked on the outside at the base with five prominences, which correspond with an equal number of little pits filled with a slightly viscid whitish fluid. There is no corolla. There are five stamens combined into a central column-like tube, from the apex of which proceed five long slender sharp-pointed processes, which are all curved one way, coloured red, and look very much like what one might imagine to be the claws of a demon's hand; on the convex side these processes bear the anthers. The fruit is a large woody 5-celled 5-valved capsule, with from fifteen to twenty seeds in each cell.



Hand-Tree (*Cheirostemon platanoides.*)

a, fruit opened; *b*, section of young fruit, showing the disposition of the seeds; *c*, pistil and bracts; *d*, flower opened to show the tube of the stamens and the five anthers (all these figures are about one-sixth less than the natural size; those which follow are, some of the natural size, and others slightly magnified); *e*, *f*, *g*, seeds; *h*, *i*, sections showing the situation of the embryo; *k*, the embryo, placed to show the cotyledons.

The singular form of the stamens and their large size have rendered this tree an object of curiosity and veneration in Mexico from time immemorial. The native Mexicans call it by the unpronounceable name of Macpal Cochiquauhitl, which the Spaniards translate Arbol de Manitas, and the English Hand-Tree. What made it a greater object of admiration was, that in all Mexico only one tree was known, which was near the town of Toluca, about sixteen leagues west of the city of Mexico. The flowers of this plant were so constantly gathered by the Indians as objects of veneration that the fruit never ripened, and it was not till the year 1801 that cuttings transferred to the Botanic Garden at Mexico struck root, and began to multiply this vegetable wonder. The original tree must be much more ancient than the conquest of Mexico, for it has been distinctly described by the Spanish historians. The people of Toluca imagine that the tree is one and indivisible, that no other was ever created, nor any other ever propagated. Seeds however have been produced from the young plants in the Botanic Garden, Mexico, whence they may now be procured without difficulty. Plants of it were thus obtained some years since by Mr. Lambert, of Boyton House, in Wiltshire, and they are not uncommon in large collections. Notwithstanding the belief of the Mexicans to the contrary, it is really found wild in Guatemala, where whole forests of it were observed near the city of that name by one of the pupils of Professor Cervantes. The Hand-Tree is said to form a very large tree, which preserves its leaves all the year round, and forms a fine shady canopy, flowering in November, December, and January.

(Hernandez, *Hist. Plant. Nov. Hisp.*, vol. ii., ed. 2, p. 531; Vetancourt, *Theatr. Mexic.*; Larreategui, *Dissert.*, June, 1795; Tilesius in *Act. Petrop.*, 5, 321, t. ix.; Humb. and Bonpl., *Pl. Æquinoct.*, i. 85.)

CHEIROTHE'RIUM. The footprints on the Red-Sandstone of Hildburghausen were referred by Kaup to a mammiferous animal under the above title. To the same origin many similar remains in England have been referred. Professor Owen is of opinion that the animal was reptilian, and that it may be regarded as identical with the *Labyrinthodon* of the same formations, of which the teeth are very characteristic. The animal was probably a Batrachian Reptile. The footprints occur with ripple marks, and what are called rain marks, on the flaggy red-sandstones of the Mersey and also in Dumfriesshire.

CHELIDO'NIUM, a genus of plants belonging to the natural order *Papaveraceæ*. *C. majus* is the only species. It is a glaucous rather hairy annual, with small yellow flowers, a siliquose capsule, and orange-coloured juice. It is not at all uncommon in waste places in this country; it is commonly called Celandine, and possesses no useful properties worth naming.

CHE'LIFER, a genus of *Arachnida* remarkable for the resemblance which the species composing it bear to scorpions. Hence Lamarck styled the order in which he placed them 'les Faux Scorpions,' associating them with *Galeodes*. They belong however to the *Trachearian* division of the class *Arachnida*. The mandibles of *Chelifer* are short, with didactylous extremities. The palpi are two, very long, and fine pointed, resembling arms, and having claws at their extremities. The maxillæ are connivent and two in number. The eyes are two in the *Chelifers* proper, as distinguished by Hermann from the species of the genus *Obisium* of Leach, which have four; they are placed at the sides of the thorax. The body is ovate, anteriorly acute, and depressed. The feet are eight.

These curious animals are very small, and resemble miniature scorpions deprived of their tails. They run fast, moving backwards, forwards, and often sideways like crabs. They live under stones, in crevices of rocks by the sea-side, under bark of trees, and in houses among old papers and old furniture. They feed upon insects. They are found in all parts of Europe.

CHE'LMON. [CHÆTODON.]

CHE'LODUS, a genus of Fossil *Mammalia* proposed by Kaup. It is of the rodent type, allied to the beaver and porcupine, and occurs in Tertiary Beds at Eppelsheim, near Mainz.

CHE'LONARIUM. [ELATERIDÆ.]

CHELONE. [CHELONIANS.]

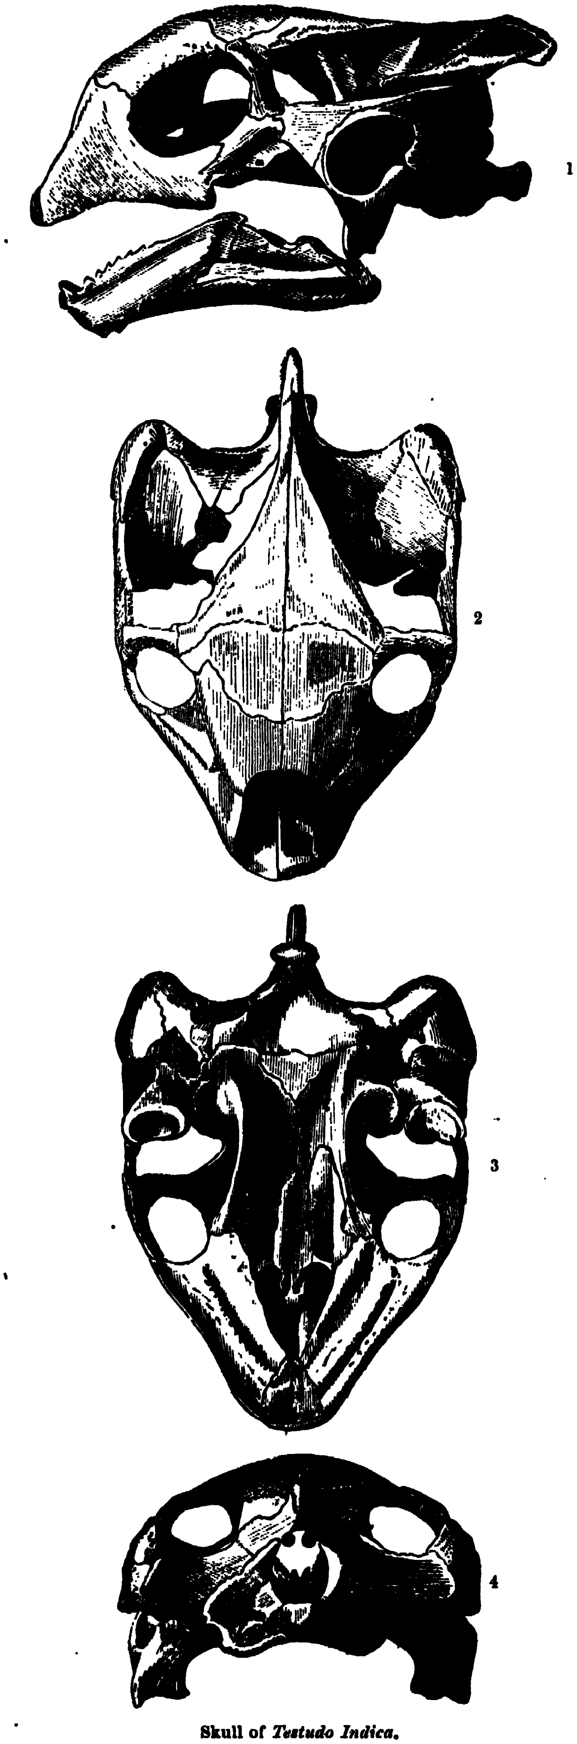
CHELONIA (Χελώνη, a Tortoise), Tortoises and Turtles, a numerous and highly interesting order of Reptiles, generally considered the first by herpetologists. They are also termed *Testudinata* (from *Testudo*, the Latin name for a Tortoise), and are distinguished at the first glance by the double shield in which their body is normally inclosed, whether they are terrestrial, fresh-water, or marine. They were all comprised by Linnæus under his genus *Testudo*.

The following account of the organisation of these animals is principally derived from Cuvier.

Skeleton.—The surface of the skull in these reptiles is continuous, being without any moveable articulations, as is the case with the Serpents and the Tailed Batrachians. But whilst this character prevails in all the genera of which the order is composed, many of those genera differ much in their cranial structure, and it becomes necessary to point out these differences, which are much greater than those which exist in the crania of the Crocodiles.

In the Land-Tortoises the head is oval and obtuse anteriorly; the interval between the eyes is large and convex; the aperture of the nostrils is large, higher than it is wide, and a little depressed backwards. The orbits, which are large, are nearly round, complete throughout, directed sideways and a little forwards. The parietal region terminates backwards in a large projecting occipital spine, and has on each side two large temporal fossæ, under which are enormous tympanic cavities; behind those cavities, and a little above, project two large mastoidean protuberances, and beneath them are the apophyses, which serve for the articulation of the under jaw. These apophyses descend vertically, and are not directed backwards as in the Crocodiles. Underneath, the basilary region is flat, the palatine concave; and upon the anterior part of this last the osseous posterior nostrils open, there being no palatine roof, and the palatine part of the maxillaries being open up to the anterior fourth of the muzzle; a disposition rendered necessary by the mode of respiration in these animals, and which as much resembles that of the Frogs as it differs from that of the Crocodiles. The occipital region is in its totality vertical, although the occipital spine, the mastoidean protuberances, and the articular condyle of the skull, which is a very projecting tubercle, render it very unequal.

The first remarkable feature in the composition of the head of the Tortoises is the absence of nasal bones. In the recent animal the external bony nostrils are narrowed by cartilaginous laminæ, which represent these bones; but in the skeleton is found immediately at their upper border the anterior frontal bone, which takes its ordinary place in the frame of the orbit, is articulated also, as ordinarily, to the ante-orbital apophysis of the maxillary bone, descends within the orbit, forms the anterior septum, which separates the orbit from the nose, and is articulated below with the palatine and the vomer, leaving between it, the maxillary, and the palatine, an oblong hole, which leads into the posterior nostrils. The osseous cavity of the nose is oblong, and formed by the maxillaries, the intermaxillaries, the vomer, the two anterior and the two principal frontals. The extent of the anterior frontals and the absence of the nasal bones are the causes that the first articulate with each other, and that they extend above the orbit and outside the principal frontals up to the posterior frontals in *Testudo Indica*, or very near it in some other species. The intermaxillaries have no ascending apophysis. They form, as ordinarily, the termination of the muzzle, and are directed backwards in the palate between the maxillaries, and even between the posterior nostrils, to the vomer. The posterior nostrils are two large apertures pierced on each side in the middle of the nasal cavity between the maxillaries, the intermaxillaries, the vomer, and the anterior frontal bones. The bottom of the cavity of the nose is covered above and closed behind by the principal frontals, which leave a large aperture between them, closed by a cartilage which permits the passage of the filaments of the olfactory nerve. Lower and laterally there is, between the frontal, the anterior frontal, and the vomer, a rather large space closed by a continuation of the same cartilage, which represents the os planum. In the Terrestrial Tortoise there is no inter-orbital simple cartilaginous septum, or nearly none; but this is not so in other sub-genera. The frontals cover but very little of the cerebral chamber, because they are short, and together form a lozenge wider than it is long. The parietals form together a pentagon, the most acute angle of which proceeds to unite itself with the occipital spine. They cover more than half of the cerebral chamber, and are directed backwards by means of a scaly suture on the occipital bone and on the petrous bone. On each side the parietal bone descends very low into the temporal fossa; there it occupies nearly all the space which the temporal wing of the sphenoid bone occupies in the crocodile, and in the tortoise there only remains a very small portion of this bone, which unites on one side to the descending portion of the parietal; on the other to the palatine, the internal pterygoid, the body of the sphenoid, the tympanic cavity, and the os petrosum. The jugal bone is articulated, as ordinarily, with the external and posterior angle of the maxillary bone. It is narrow and continued under the orbit, behind which it encounters the posterior frontal bone, which completes the frame in this part, and the squamous portion of the temporal bone, which forms by itself the whole zygomatic arch, as may be seen in many of the *Cetacea*. The temporal bone widens to unite itself to the tympanic cavity, which is extremely large. It forms a frame which is nearly completely bony for a large tympanum; and below this frame it descends in form of an apophysis for the articulation of the lower jaw. This frame leads into a vast cavity, completed only at its upper posterior angle by the mastoidean. At the bottom of this cavity is a hole through which passes the ossiculum auditûs to arrive at a second cavity, formed externally by the bone of the tympanic cavity, on the internal side by the petrous bone and the occipital bones, below a little by the sphenoid bone, and closed backwards by cartilage. It is a second part of the tympanic cavity which is thus divided by a constriction, of which we have examples among the mammals, especially in the genus *Felis*, but the communication between the two parts is less narrowed than in the Tortoise. The tympanic bone forms besides a considerable part of the posterior walls of the temporal fossa. Between it and the parietal the petrous bone shows itself in this same temporal fossa, and the cranium is closed behind by the occipital bone, which is here divided into six bones, not into four; for the lateral occipitals are each divided into two parts, the most external of which Cuvier terms the exterior occipital. The fenestra ovalis is, he observes, common to the petrous bone and this exterior occipital; as, in the crocodile, it is common to the petrous bone and the ordinary lateral occipital: the fenestra rotunda, on the contrary, is pierced in the exterior occipital, as it is pierced in the lateral occipital of the crocodile. The two bones contribute to the formation of the cell of the labyrinth with the upper occipital, as the petrous bone and the lateral occipital contribute to it in the crocodile. In both genera the great aperture for the exit of the fifth pair of nerves is in front of the petrous bone, between it and the temporal ala. In the Turtle this hole is between the petrous bone and the descending part of the parietal bone. The ossiculum auditûs is simple, as in the crocodile, and formed of a slender stem, which widens at the point of its approximation to the fenestra ovalis, and which is there applied by a round and concave surface, so that it has nearly the figure of a trumpet. The Eustachian tube is entirely cartilaginous or membranous. It commences in the external chamber of the cavity, above, by a large notch of the posterior border of the tympanic bone, near the edge of the tympanum itself, and is directed obliquely within, passing between the bone of the cavity and the depressor muscle of the lower jaw, to a notch of the lateral and posterior border of the pterygoid bone, whereby it penetrates into the back of the fauces, on the side, close to the articulation of the lower jaw, but far enough from its congener, and especially very far behind the internal nostrils. On the palate, or rather, behind the roof of the back of the mouth, may be seen the orifices of two tubes, under the form of two small holes separated from each other.



Skull of *Testudo Indica*.

1, Profile; **2**, seen from above; **3**, seen from below; **4**, seen from behind.

Reverting to the lower surface of the cranium, behind the maxillaries and the frontals, posterior to the two sides of the vomer, are the palatines, surrounded behind and externally by the pterygoid bones, which last extend along the external border of the palatine to the maxillary bones. The rest of the pterygoids covers the lower surface of the cranium between the two tympanic cavities and the two temporal alæ, leaving exposed to view behind only a triangular part of the body of the sphenoid. The olfactory and optic nerves have their exit by the cartilaginous septa of the cranium, and not by any particular opening in the skull. Cuvier thinks that it is the same with the third and fourth pairs: the sixth goes forth by a small canal of the body of the sphenoid bone. The fifth pair has a great hole between the petrous bone and the temporal ala divided into two externally. There is at the external border of the palatine bone a hole analogous to the pterygo-palatine.

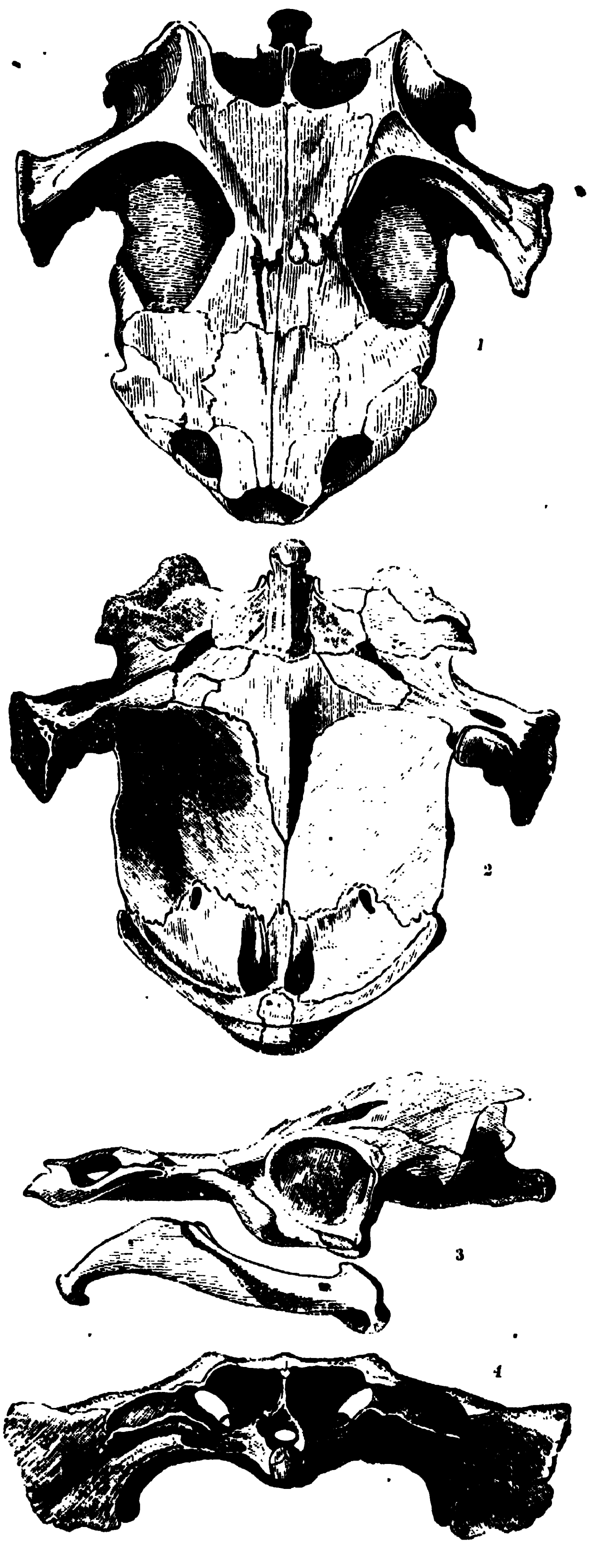
Internally, the cerebral cavity is higher than it is wide; the bottom of it is very entire: but, in front, in the sphenoid, there is a deep fosset for the pituitary gland, a kind of saddle. From the sides of this part spring the cartilaginous septa, which in going to form a junction with the ante-cerebral partition of the frontal bone, close the cavity of the cranium, support the whole anterior part of the encephalon, and occupy the place of the cribriform plate, of the orbital alæ; or otherwise, the anterior sphenoid, and the greater part of the temporal alæ, of which another considerable part is replaced by the descending portions of the parietal, so that what remains does not participate in the formation of the chamber of the cranium except a little in front of the hole for the fifth pair of nerves. There is no more bony trace of the anterior sphenoid than in the crocodile.

In the *Emydes*, or ordinary Fresh-Water Tortoises, the head is more flattened. The principal frontals, although they are wider than they are long, do not always reach to the border of the orbit, as is, for example, the case in the *Testudo* (*Cistudo*) *Europæa;* the posterior frontal is wider. The frame of the tympanum is not complete, and in lieu of a hole there is a fissure for the passage of the ossiculum auditûs from one hollow of the cavity to the other. The basilary and palatine regions form but one plane; the palatines not being even concave. Cuvier observes that *Testudines scripta, picta, scabra, dorsata, centrata, clausa,* and *virgulata,* belong to this category. Certain *Emydes,* he remarks, *Emys expansa* for instance, tend to the Sea-Tortoises, or Turtles, and the Fresh-Water Tortoises, and yet exhibit characters peculiar to themselves.

In the *Trionyces,* or Soft Tortoises, the skull is depressed, and elongated backwards; the muzzle, pointed in certain species (that of the Nile for instance), is short and rounded in some others. The intermaxillary bones are very small, and have neither nasal nor palatine apophysis; there is behind them a large incisive hole. The maxillaries unite upon the palate for a rather long space, so that the posterior nostrils are more backwards than in the Land-Tortoises. The palatines do not unite below to prolong the palate; they are hollowed into a demi-canal anteriorly, and less extended than in the Land-Tortoises.

The principal character of the Marine Tortoises, or Turtles, is that a lamina of their parietal, their posterior frontal, their mastoidean, their temporal, and their jugal, unite together, and with the tympanic cavity, by sutures, to cover the whole region of the temple with a bony roof, which has no solution of continuity. Their muzzle being shorter than in other tortoises, and their orbits much longer, their nasal cavity is smaller, and as wide as it is high and long. Its posterior wall belongs entirely to the anterior frontals, and it is between them that the olfactory nerves are introduced. The bony tubes of the back nostrils commence in the lower part of this posterior partition, and, like the palatines, have a palatine part or lower lamina; these tubes are rather longer, more directed backwards, and bear less resemblance to simple holes. It results also from the size of the orbit that the inter-orbital membranous or cartilaginous space is more extended.

The most heteroclite skull among the tortoises is that of the Matamata (*Testudo fimbriata, Chelys fimbriata*). Extraordinarily large and flat, it seems to have been crushed. The very small orbits are close to the end of the muzzle. The posterior region of the cranium is elevated; and the two tympanic bones, in form of trumpets, widen out on each side of the cranium. The temple is a wide horizontal fossa, not deep, and not at all covered, except behind by the union of the posterior angle of the parietal with the mastoidean bone; and, what is peculiar, Cuvier observes, to this sub-genus, this fossa is not framed in externally, because there is no temporal bone, or at least it is reduced to a simple vestige. The two maxillaries form together a transversal arch, in the middle of which, below, is a single intermaxillary, and, above, the external aperture of the nostrils, which is continued into a small fleshy proboscis. The two palatine bones, and, between them, the vomer, fill below the concavity of this arch, and have in front the two back nostrils well separated, but which the palatines do not encircle below. At the posterior border of the palatine is a rather large pterygo-palatine hole. The anterior and posterior frontals form the upper part of the orbits. The principal frontals advance between the anterior frontals to the edge of the external nostrils. There is no more nasal bone than in the other tortoises. The jugal proceeds from the posterior angle of the orbit between the maxillary and posterior frontal, beyond which it does not go, touching a little behind and below the pterygoidean; but not forming any projection behind to border the temple. This last is in this manner separated from the orbit by a postorbital branch of excessive width, and which takes in the totality of the posterior frontal and the jugal bones. The posterior frontal articulates itself to the pterygoidean by its external posterior angle. The rest of its posterior border is free, and is continued with that of the parietal to cover a wide and flat canal of communication, proceeding from the temple to the orbit, and formed below by the pterygoidean and palatine bones. The two pterygoideans are enormous. They form the greatest part of the base of the cranium and of the bottom of the temple. Their external border is curved in its anterior part for its continuation with the free border of the posterior frontal; there



Skull of Matamata (*Chelys fimbriata*).

1, seen from above; 2, seen from below; 3, profile; 4, seen from behind.

are neither orbital nor temporal alæ. The parietal bones, which form above a great rectangle, unite by their descending portions to the palatines, the pterygoideans, the petrous, and the upper occipital bones. They form by themselves nearly the whole roof of the cranium. Following the pterygoidean, the temple is bounded behind by the tympanic bone or the tympanic cavity, which resembles in part a trumpet. The frame of the tympanum is complete. A hole in the posterior wall suffers the ossiculum to pass into the second chamber, which, in the skull, is only a long groove of the posterior surface of the cavity, which terminates in a hollow, in the formation of which the petrous bone, the external occipital, and the lateral occipital concur. It is not closed behind, except by cartilage and membranes; and in the wall of the side of the cranium are pierced the two fenestræ, as ordinarily. Above this hole of the first chamber, by which the ossiculum passes, is another which conducts into the mastoidean cellule, which, on account of the outward projection of the tympanum, is found within and not behind. The occipital spine is a short vertebral crest, and the mastoidean tubercles are transversal crests, which belong entirely to the mastoidean. Even in large individuals the six occipitals ordinary to the tortoises may be distinguished. Below, the smooth and nearly plane cranium presents a sort of regular compartment, formed of the intermaxillaries, the maxillaries, the vomer, the palatines, the pterygoideans, the sphenoid, the petrous bones, the tympanic cavities, the basilary, and the lateral and external occipitals. Behind the ceiling of the temple the petrous bone forms a square compartment between the pterygoidean, the tympanic cavity, the external occipital, the superior occipital, and the parietal bones.

The lower jaw of the tortoises is divided in a manner which it is not very easy to refer to that manifested in the crocodile, to which, Cuvier observes, that of the birds has a much more striking relation; but the bird's jaw, he adds, also approaching to that of the tortoises, aids us in referring it to a common type. The space occupied in the crocodile by the two dental and the two opercular bones is filled in the Marine Tortoises, the Fresh-Water, and Land-Tortoises, as well as in the *Trionyces*, with a single bone only, the analogue of the two dental bones. Cuvier never saw in all these sub-genera, even in their youth, any trace of symphysis: the bone is continuous in the tortoises, as in birds. The Matamata, or *Chelys*, on the contrary, preserves in every age a division at the anterior part. The opercular bone always exists, as in the crocodile, at the internal surface; but it is carried farther backwards, and attains to the posterior extremity. Beneath it is the angular bone forming the lower edge of the jaw. That which Cuvier names the surangular bone occupies the external surface of this part of the jaw, and proceeds also to its posterior extremity, but only touches the angular bone quite behind, and in becoming separated on the two anterior thirds by a long point of the dental bone. Above, and towards the back part, between the opercular and surangular bones, the articular bone is situated, as in the birds; but in the tortoises it is reduced to smaller dimensions, only serving for the articulation and for the insertion of the depressor muscle, or the analogue of the digastric muscle. The coronoid apophysis does not belong at all to the surangular bone in this order, but to a bone placed between the dental, the opercular, and the surangular bones; and in front of the aperture by which the nerves enter the jaw, an opening, which is here found at the upper border, instead of being, as in the crocodile and the birds, at the internal surface. This bone, which is not found in the birds, can only respond to the complementary bone in the crocodile. Cuvier saw in the *Emys expansa* the surangular, the opercular, and the articular bones anchylosed, and their sutures effaced, at a period when all the others were still visible. The general form of the bony jaw corresponds nearly to what is seen externally. More pointed in the *Trionyces* and *Chelone Caretta*; more obtuse, more parabolic, in *C. Mydas* and the Land-Tortoises; semicircular in front of the coronoid apophyses in the Matamata; it differs also in the furrow with which it is hollowed. This furrow is narrow, deep, and equally wide in the Land-Tortoises; widens and deepens towards the symphysis in *C. Mydas;* and is entirely wanting in *Trionyx*, *C. Caretta*, &c.

The os hyoides of the tortoises is more complicated than that of the crocodiles, and varies singularly in form from one genus and even one species to another. It is in general composed of a body itself, sometimes subdivided into many pieces, and of two, sometimes three pairs of horns: and under the anterior part of its body is, besides, suspended a bone or a cartilage, sometimes double, which is the true bone of the tongue analogous to that seen in the birds, but articulated in them in front of the body of the os hyoides, whilst in the tortoises it is suspended below it. The greatest horns (the anterior pair when there are only two, the middle when there are three, representing the styloïdean bones) embrace the œsophagus, and mount behind the muscles which are the analogues of the digastrics, or depressors of the lower jaw, but without being fixed otherwise than by their proper muscles. The Land-Tortoises have the body of the os hyoides wider, its anterior portion longer, and want the small anterior horns, whilst the anterior angle is very much developed. In the middle of the disc are two round spaces, which in certain tortoises, the *Testudo Indica* for example, are only more delicate; but which in the others, *Testudo radiata* for instance, are absolutely membranous.

In some Fresh-Water Tortoises, *Testudo Europæa* and *T. clausa* for example, the body of the bone is longer than it is wide; and has in the front a small membranous space, and at its anterior angles the small lateral horns. Sometimes two or even four osseous nuclei are there formed.

The os hyoides of *Trionyx* differs still more. Its body is composed in front of a cartilaginous point, under which is suspended a great lingual oval cartilage. At the base of this a rhomboidal osseous piece adheres on each side, which piece represents the anterior horns, and afterwards four others forming a thick disc, concave above, wider in front, and notched on the sides and behind. At the anterior angles of this disc adhere the middle horns, and to the posterior angles are attached the posterior horns: all four are very bony. The middle are formed by a long piece, which is compressed, arched, and terminated by a small cartilage. The others are wider, flatter, and prolonged by a cartilage, in the substance of which are encrusted in a row from five to six bony nuclei, which are round or oval, very hard and very distinct; so that the entire bone comprehends twenty different osseous pieces, which appear to remain distinct to old age.

The most singular of all these is that of the *Chelys*, and is very early entirely ossified. Its body is composed of a long narrow prismatic piece, hollowed above by a canal where the trachea runs. In front this piece is dilated, and carries on each side two angular portions, four in all, without counting the piece itself. The two intermediate ones unite in front, leaving between them and the principal body a membranous space on which the larynx reposes. The lateral portions, Cuvier observes, represent perhaps the small anterior horns. It is on the angle which they form with the dilatation of the principal body that the middle horns are articulated; these last are very strong, prismatic on their internal moiety, and then slender, and terminated by a bony and pointed piece, distinct from the rest of the horn. The posterior horns are articulated at the posterior extremity of the prism formed by the principal body. They are long, strong, slightly compressed, and curved into an arch.

Under the anterior and dilated part is suspended the true bone of the tongue, formed in front of a semicircular cartilage, and behind of two bony pieces in form of a crescent, the internal angle of which is prolonged into a sort of tail or pedicle, which lies under the prismatic body of the os hyoides.

In the Turtles, *Chelone Caretta* for instance, the body of the bone is in the form of an oblong buckler, concave above for the support of the larynx and the commencement of the trachea, and drawn out in front into a point which penetrates into the flesh of the tongue in passing upon the lingual bone. It presents on each side an angle for carrying the anterior horn, which is very small; the great horn curved into an obtuse angle for going round the œsophagus and jaw, more bony than all the rest of the apparatus, is articulated to the middle of the lateral border of the body of the bone, and its free or upper extremity is terminated by a small cartilaginous articulation. The posterior horns are articulated to the posterior angles. They are cartilaginous, flat, rather wide, and scarcely arched.

Bones of the Trunk: Dorsal Buckler, or Carapace.—The wide differences prevalent in the modification and arrangement in the bones of the head in this order lead one to expect, as the great French zoologist observes, proportional differences in the rest of the skeleton. The cranial differences are, as he remarks, greater perhaps than obtain among the whole of the mammals, and most certainly are more extensive than can be found in the whole class of birds.

The general distinguishing character of the Tortoises, that which separates them from all the *Vertebrata*, is the external position of the bones of the thorax, enveloping with a cuirass or double buckler the muscular portion of the frame, and serving also as a protection for the shoulder-bones and the pelvis.

The dorsal buckler is principally formed of eight pairs of ribs, united towards the middle by a longitudinal succession of angular plates, which adhere to the annular parts of so many vertebræ, or even form a part of them; but it is remarkable that these annular portions alternate with the body of the vertebræ, and do not correspond directly with them.

The ribs are inlaid by means of sutures into these plates; they are also united with each other, on the whole or a part of their length, according to the species, and even in each species according to the ages of the individuals. There are eight anterior vertebræ which do not enter into this conjunction. The first seven (the ordinary cervical) are free in their movements. The eighth, which may be regarded as the first dorsal, is placed obliquely between the last cervical and the first of the fixed vertebræ of the dorsal buckler, which shortens it anteriorly; behind, its spinous apophysis is elongated, and enlarges a little to attach itself by synchondrosis to a tubercle of the first of the plates of the intermediate series of the plastron.

The first of these fixed vertebræ, which is the second dorsal, is still rather short, and carries also its proper annular part, the spinous apophysis of which, shorter than the preceding, attaches itself to the second plate by a cartilage. This second plate, narrower than the first, forms but one bone with an annular part which is below, and of which the anterior portion is articulated by two small apophyses with the articular apophyses of the second dorsal. This, properly speaking, is the annular portion of the third dorsal vertebra; but the body of this third vertebra is only articulated by its anterior moiety with the posterior moiety of this third annular part, and by its posterior moiety it is articulated to the anterior moiety of the fourth annular portion; and this alternative continues, so that the body of the fourth vertebra responds to the annular portions of the third and the fourth, the body of the fifth to the annular portions of the fourth and fifth, and so on to the tenth.

But it is necessary to distinguish in the ribs the plate included in the buckler, and a small branch which proceeds from its lower surface, and which represents what is termed the head of the bone in the ordinary ribs. This head is always articulated between two bodies of vertebræ. The first of all these ribs has only this small branch, without having any plate belonging to it in the buckler, excepting only in some of the *Emydes*, where may be seen, between the first and second longitudinal plate, and the first or second widened rib, a small piece which can only represent the enlarged portion of this first rib, but which does not belong to its head. It is articulated between the eighth vertebra or first dorsal, and the first fixed vertebra, and by its other extremity applies itself to the internal surface of the second rib. This last has a plate which incorporates itself by its anterior border with the first of the longitudinal series, by its spinal border with the second piece of that series or the annular portion of the third vertebra, and by its head between the body of the second vertebra and that of the third. The succeeding ribs observe the same law, are articulated by means of their head between the body of one vertebra and that of the succeeding vertebra, and incorporate themselves by means of their dilated part with the plate which represents the annular portion of the second of these two vertebræ: and this, Cuvier observes, is a return to the general law; for in man and in the quadrupeds the ribs are articulated by their head between two vertebræ, and by means of their tuberosity, with the transverse apophysis of the second of the two. The dilated portions of the ribs of the tortoise, in the part where they are incorporated with the plates of the longitudinal series, represent, then, the tuberosities of the ribs of mammals. The ninth plate of the longitudinal series, which belongs to the tenth dorsal, is the last with which a pair of the dilated ribs is incorporated; and this last is the ninth in all, or the eighth of those which enter into the composition of the dorsal buckler. It is directed from its posterior border backwards, and embraces again the succeeding plates, with the external edges of which it becomes incorporated: but these three plates do not, any more than the first, serve to complete the vertebral canal.

The tenth rib, attached between the bodies of the tenth and eleventh vertebræ, produces no plate and enters not into the composition of the dorsal buckler. Like the first, it has only a portion of the head, and is joined by its other extremity to the internal surface of the ninth.

The eleventh vertebra after the cervical is the only one that can be termed lumbar; it carries no rib. In the Turtles, its annular portion again gives a plate to the longitudinal series of the dorsal buckler, and is the tenth and the smallest of the pieces of this series. The twelfth and thirteenth vertebræ are the sacral. At their sides are attached two lateral pieces sufficiently similar to the heads of the ribs, but stronger, especially the first, and convex at the end, in order to their union with the posterior and upper angle of the ossa ilii. Their annular portion is close and complete, and is not incorporated with the plates of the buckler which follow that of the eleventh vertebra. The vertebræ of the tail are free, like those of the neck: hence the plates of the longitudinal series, which follow the tenth, do not adhere to the vertebræ, and, if they belong thereto, only so belong by a metaphysical relation, and accordingly they may be considered as having been dismembered. So of the first of all the plates of the series. It only furnishes an attachment to the annular portion by synchondrosis, otherwise close and complete, of the first dorsal vertebra; and if one would regard it as belonging thereto, it would be necessary to consider it as dismembered.

The Turtles have three longitudinal plates after the tenth, making thirteen in all; but the second is sometimes divided into two, and the ninth also, which increases their number to fifteen.

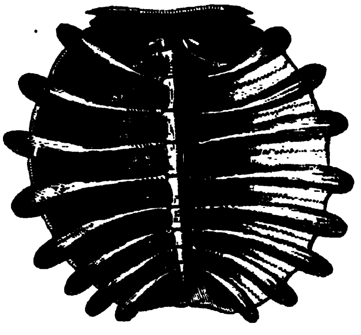
Cuvier found fourteen in some of the *Emydes*, the *Emys serrata* for instance; but the eleventh and twelfth, he adds, are very small in them. There is but a single one after the tenth in the Land-Tortoises and the *Chelydes*, so that they have only eleven in all. It sometimes happens that one or two of these plates are not seen externally. Thus in the Box-Tortoises, the two ribs of the last pair are joined to each other, and thus cover the ninth plate; and in this respect many modifications occur in the same species; of which Bojanus has, in his third plate, given many examples taken from the European Tortoise.

In *Chelys* the last and penultimate rib are attached to the eighth plate, and the ninth remains hidden. In both cases the tenth and the eleventh subsist as ordinarily.

In the Turtles, the eight pairs of ribs and the thirteen plates of the longitudinal series form a slightly convex oval buckler, a little narrowed backwards. The ribs are not incorporated throughout their length, a narrow fraction remains towards their exterior, and the intervals between this portion and that of the anterior and posterior ribs are filled up by a cartilaginous membrane only. It is only in extreme old age that some are widened to the end. Cuvier had sometimes seen the first three and a part of the fourth in this state.

In the Fresh-Water Tortoises and in *Chelys* the buckler is entirely filled up in time, and the ribs incorporate themselves throughout their length, between each other and with the marginal pieces. The ossification proceeds still faster in the Land-Tortoises, and it is only in their youth that vacant spaces are observed between the external parts of their ribs.

The Sternum Plastron, or Breast-Plate is always composed of nine pieces, of which eight are pairs, and the ninth is odd and always placed between the four anterior ones, with the first two of which it generally coheres, when it is not articulated with the four.



Carapace of *Trionyx*, seen from below.

These nine pieces vary much in figure according to the genera and species.

In the Land and Fresh-Water Tortoises and in *Chelys* they only leave vacancies between each other in early youth, when they are formed by bony rays shooting in various directions in the still cartilaginous disc of the plastron, like the bones of the cranium in the fœtus of mammals; but, with age, these rays join each other from every side, and form a disc compact in all its parts, which unites itself by a more or less considerable extent on each side to the dorsal buckler.

In the Turtles, and in the *Trionyces*, or Soft Tortoises, these radiating expansions do not unite throughout; and even when the four pieces on each side unite together and the odd piece is joined to those of the first pair, there remains in the middle, between them all and on each side between them and the dorsal buckler, great spaces which are filled up by cartilage only.

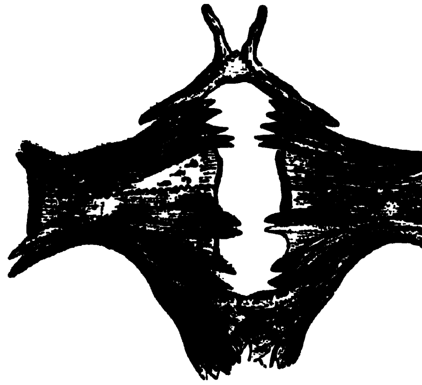
Vertebræ.—The atlas is composed of four pieces. The first two, united above in a slight spinous prominence, after having surrounded the vertebral canal, and each having given backwards its articular apophysis, concur with a third very small one in the formation of a ring for the reception of the condyle of the head: Cuvier calls it a ring, because in the skeleton this fosset is open, and its bottom filled by a fourth piece, which is a true body of a vertebra without the annular portion, and which, presenting an anterior convex surface in the space here noticed, is articulated behind by a concave surface on the body of the axis. This piece, analogous to what we have already seen in the crocodile, represents, he observes, the odontoid apophysis of the axis of mammals. At their junction, there is besides, attached below, a small bone formed nearly like a patella (rotule).

The axis and the succeeding vertebræ are composed of a nearly rectangular body, carinated below, concave in front, convex behind, and of an annular portion, which remains distinct from the body throughout life, by means of two sutures, is elevated above by a crest in lieu of a spinous apophysis, and whose anterior articular apophyses, placed at first under the posterior portions of the preceding vertebra, raise themselves obliquely to embrace them slightly up to the sixth, and nearly resume their horizontal position in the two succeeding ones. At the anterior angle of each side of the body is a small facet, common to the body and the annular portion.

The vertebræ adhering to the dorsal buckler have their body wide and feebly carinated in the Marine and Fresh-Water Tortoises: in these last it is even flattened in the anterior ones. It is also wide and with but little convexity in *Trionyx*, and *Chelys* has it wide and elevated longitudinally into a small crest. But there are Land-Tortoises (*Testudo geometrica* and *T. radiata*) in which it is excessively compressed, and does not even join itself throughout, except by a membranous partition, to the pieces of the middle row of the buckler, these pieces only affording each two narrow laminæ, and descending on each articulation of the two bodies. It is in a fold of the lower portion of this membrane, between these vertical laminæ, and in a semicanal hollowed at the upper part of the bodies, that the spinal marrow goes.

In the other sub-genera the pieces of the longitudinal series of the dorsal buckler afford more complete vertical partitions, which form with the bodies a continuous bony canal, the nerves of which go out through holes which remain between the laminæ.

The sacral and caudal vertebræ are each composed of a body, concave before and convex behind, of an annular portion, squarely flattened, and without a spine above, the anterior articular apophyses of which obliquely embrace below the posterior apophyses of the preceding vertebra, and of two transverse short apophyses, articulated on each side on the suture, which joins the body to the annular ring. Cuvier counted 23 caudal vertebræ in *Testudo Græca*, *T. Indica*, and other Land-Tortoises, and as many as 27 in *Testudo radiata*. He states that there were only 18 in the Fresh-Water and Marine Tortoises which he examined.



Sternum of *Trionyx*.

Sternum of *Cistudo*.

Bones of the Extremities.—The bone which goes from the dorsal buckler to the sternum is suspended by a ligament under the dilatation of the second rib, but in front of the first, which, as we have seen, consists only of a head articulated under the second; so that in some respects this bone is outside the thorax. There is sometimes in the ligament by which it is attached one, and even two, peculiar bones. This bone is at first nearly cylindrical: it proceeds forwards, and after having afforded on its external surface a portion of the articular facet which receives the head of the humerus, it goes with a more or less strong inward bend to attach its other extremity to the internal surface of the sternum, towards the lateral angle of the odd piece. The rest of the facet for the articulation of the humerus is furnished by another bone, which is directed more or less obliquely backwards and towards the mesial line, widening into a fan-shape, and which thus lies nearly parallel to the sternum. The osseous branch which comes from the bony buckler, is, according to Cuvier's self-corrected opinion, the shoulder-blade, and the part which it offers beyond the articular fosset is its acromion. The flattened bone which is directed backwards is, he adds, incontestably the coracoid bone: and he further remarks that all the muscles which proceed from these bones to go to the arm are respectively the same as in birds, whatever changes they have undergone in their position relatively to the horizon in their size and in their figure. Cuvier considers that it remains to be known whether there is a clavicle or not.

The three-branched shoulder, the nearly cylindrical shoulder-blade, the acromial portion nearly equal in volume to the rest of the shoulder blade, are characteristic of the Tortoises. There is nothing parallel to this conformation in the other animals, because there is no other shoulder situated within the thorax. The varied forms of these parts afford, Cuvier observes, very good characters for the subgenera; and he details the modifications characteristic of the Marine Tortoises, the Land-Tortoises, the Fresh-Water Tortoises, *Chelys*, and *Trionyx*.

The humerus of the Tortoises is required to turn singularly upon its axis, in order to place the fore foot in the position required by the bony cuirass, which only leaves a narrow passage for it. The result is that its internal tuberosity is become posterior and superior, and that the external tuberosity is become internal and also posterior. The head of the bone goes out of the axis more than in any other animal, and that towards the posterior face which in the ordinary position is the superior one. It presents the segment of a sphere, and is very convex. The two tuberosities are very large, very projecting, and leave between a concavity, as there is one backwards, between the condyles of the humerus in the greater part of the mammals. The internal tuberosity—become, as has been pointed out, posterior is the largest. It has the form of a long obtuse crest, analogous to the deltoidean, and which receives the same muscles. The other tuberosity forms a crest also, but much shorter. Both are near the head. The body of the bone is bent; and its concavity, which in man would be anterior, is ordinarily found inferior. The opposed surface is convex. Above it is a small hollow opposite the end of the fossa, which is between the two tuberosities. The lower part of the bone is widened and a little flattened from before backwards. On the external border is a furrow, not much developed in the Land-Tortoises; deeper in the *Emydes*, the *Chelydes*, and the *Trionyces*; and which in the Marine Tortoises nearly separates the lower head of the bone into two unequal parts. This furrow, Cuvier observes, is perhaps the best character for distinguishing the lower part of the humerus from that of the femur, which is without it, but which in every other point offers only very slight differences. Its lower head, transversely oblong and of uniform convexity, receives the bones of the fore-arm, but without offering two distinct facets.

The *Trionyces* do not differ from the Land-Tortoises, excepting in having the tuberosities more apart. Other differences are manifested in *Emys* and *Chelys*, for which we refer to Cuvier's work, but the humerus of the Marine Tortoises cannot be passed by without particular notice, for it differs from that of all the other *Testudinata* in being not bent longitudinally, but nearly straight; in having its great tuberosity (the analogue of the small or internal tuberosity in man) longer, overreaching the head, and resembling an olecranon; and, lastly, in having the other tuberosity shorter, and representing a chevron-shaped crest.

There are always two bones in the fore-arm, but they have little motion one on the other. They are placed, when the animal progresses, so that the ulna forms the external and the radius the internal border of the arm.

The radius has a semicircular, slightly concave, upper head, a somewhat slender body, and the lower head compressed and cut, as it were, obliquely, so that it is shorter on the ulnar side.

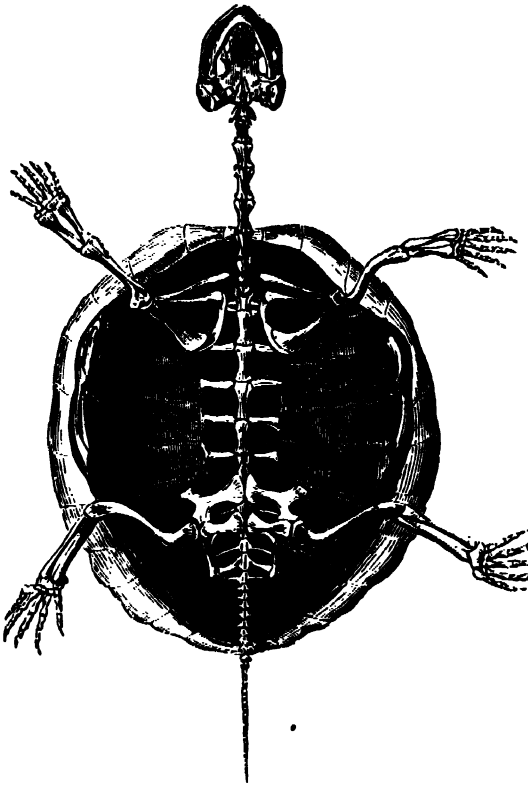
The ulna is compressed. Its upper head is triangular and cut obliquely, so that its external border is longer upwards than the radial border without having a true olecranon. This border is trenchant. The lower one is cut square. Differences occur, as in *Trionyx* and the *Chelones*, or Marine Tortoises.

The pelvis is always composed of three distinct bones, contributing, as in the *Mammalia*, to the composition of the cotyloid fossa, namely, an elongated os ilium, which attaches itself by ligaments to the transversal processes of the sacral vertebræ and the neighbouring part of the eighth pair of the dilated ribs; a pubis and an ischium, which are directed, widening as they proceed towards the plastron, and are each united to its similar piece. At the point of union for the formation of the cotyloid cavity, each bone has three faces; one for each of the two others and one for the cavity. On the rest of the length the os ilii is oblong, the ischium proceeds, widening as it goes, directly towards the symphysis, and the pubis, after first directing itself forward, makes a curve towards the symphysis, and widens also to reach it. Various differences occur in this part of the skeleton in the Land and Marine Tortoises, in *Chelys*, and in *Trionyx*.

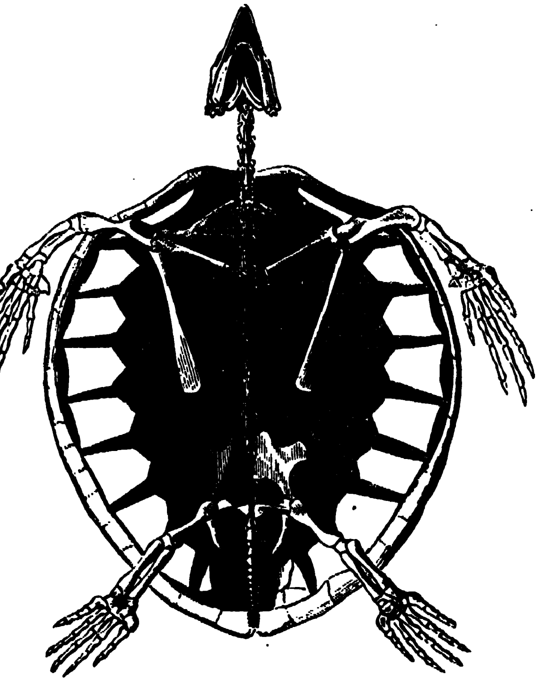
The femur might be easily mistaken for the humerus of a mammiferous quadruped. Its oval head leaves the body of the bone, without being precisely separated from it, by a narrow neck. In lieu of the trochanter there is a transverse crest, but little elevated, separated from the head by a semicircular depression. The middle of the bone is delicate and round, and the lower part compressed from before backwards, widening by degrees to form the lower head, which is a transverse portion of the cylinder a little inflected backwards. Differences of modification occur in the Fresh-Water and Marine Tortoises.

The two bones of the leg are nearly straight. The tibia is larger and nearly semicircular above, becoming again slightly larger below; the fibula is more compressed and wider below. The first presents a slightly concave uniform surface, the other one which is slightly convex and rhomboidal at the astragalus. Modifications occur in the Land-Tortoises, in *Chelys*, in *Trionyx*, and in the *Chelones*.

Bones of the Fore Foot.—The differences in the mode of progression required corresponding variations in the bones of the fore and hind feet especially. Accordingly we find that in the *Chelones* all the bones of the waist are flat and cut nearly square. In the first row are two bones adhering to the ulna, and in the last row five smaller ones, supporting the five bones of the metacarpus. There is besides an intermediate bone under the first ulnar bone, and upon the second and third of the last row. Cuvier observes that this would seem to correspond with that dismembered trapezoidal bone which is found in the monkeys. Lastly, there is a great semilunar bone out of the rank, adhering to the external border of that which is above the metacarpal of the little finger. It is a true pisiform bone, although a little descended. Between that which is on the metacarpal of the thumb and the radius there is for a long time nothing but ligaments, and one does not see the great semilunal scaphoidal which may be observed in the other sub-genera: but with age a small radial bone shows itself in this place. Very large individuals have also the two penultimate bones of the second row anchylosed together. The metacarpal of the thumb is short and large: the others are long and slender. The little finger has two phalanges, and is not larger than the thumb; the three others are elongated, especially the middle finger; and the whole result is a pointed hand, which has the unguial phalanx of the thumb and forefinger only armed with a claw.



Skeleton and Carapace of *Cistudo vulgaris*, seen from below.



Skeleton and Carapace of *Chelone Caouana*, seen from below.

In the Land-Tortoises there are but two phalanges on each finger. There are found in the carpus a great radial or semilunar scaphoidal, two ulnar bones nearly square, five bones of the second row supporting the five metacarpals, and an intermediate bone placed between the great radial, the first cubital or ulnar, and those which carry the third and fourth metacarpal. This intermediate bone, according to Cuvier, is often anchylosed with the semilunar scaphoidal bone. The bones of the metacarpus are even shorter than the phalanges.

In the Fresh-Water Tortoises the three mesial fingers have their three phalanges well developed; but there are only two belonging to the thumb and the little finger. The metacarpals are rather long, and the two external ones are carried on a single bone of the carpus: nevertheless the last row consists also of five bones, because there is one, very small, externally on the side of the thumb. In the first row the ulna, in the European Tortoise at least, carries four bones—two large ones, a small intermediate one, and another small one out of the rank; but there are other species, *Testudo clausa* for instance, where the two small ones do not appear. The great radial or semilunar scaphoidal passes partially under the two ulnar bones.

The *Chelydes* have the hand formed nearly like the Fresh-Water Tortoises, except that their radial bone is small, and re-enters towards the inside of the carpus at the side of the bone named by Cuvier intermediate; and that the little finger has, like the three intermediate ones, three phalanges.

The *Trionyces* have also the radial bone re-entering at the side of the intermediate bone. Their first three fingers have their three phalanges large, wide, and pointed to carry the claws; the fourth has four phalanges, all rather slender; and the last three.

Hind Feet. Cuvier remarks that in the *Chelonia*, generally, the calcaneum is without any backward prominence, so that their tarsus is flat like a carpus.

In the *Chelones* it is composed of six or seven bones, if the first of the little toe be counted: two in the first row, of which the largest, nearly rhomboidal and answering equally to the tibia and fibula, is the astragalus; the smaller, which is square and articulated only to the fibula, is the sole vestige of a calcaneum. In the second row there are four: three wedge-shaped for the metacarpals of the great toe and the two next toes, and one larger for the two last metatarsals. The bones of the metatarsus of the great and little toes are shorter than the others, and singularly wide and flat. That of the little toe however may be taken for one out of the rank of the tarsus. In this last case the little toe would have but two phalanges, otherwise three like the others. The great toe has but two. It carries a claw, and so does the next toe. The two succeeding toes have still their last phalanges rather large, although without claws, but the last has that phalanx very small.

In the Land-Tortoises the bone analogous to the astragalus is larger and thicker; and the fibular bone on the analogue of the heel is smaller. The four other bones exist, and that here called the metatarsal of the little toe seems to make up the suite by its position and figure. It sometimes carries a vestige of a toe formed of one piece, which seemed to Cuvier to be wanting in many species. The metatarsal of the great toe is very short and not flattened; the others are rather longer. None of the four existing toes has more than two phalanges.

The tarsus of the Fresh-Water Tortoises is nearly the same, except that the fibular ossicle, or calcaneum, when it is not united to the astragalus, is larger; that the ossicle which serves as a vestige of the little toe is longer; and that the three toes which succeed the great toe have their phalanges very distinct.

In the tarsus of the *Trionyces* the fibular bone descends outside the three cuneiform or wedge-shaped bones, and carries half the head of the third metatarsal and the whole of that of the fourth. At its external border a large square bone adheres, that about which Cuvier expressed a doubt whether it was a metatarsal bone or one out of the rank. It carries the fifth metatarsal on the first phalanx of the little toe; but in this case the little toe would have three. It is true, Cuvier adds, that the fourth toe has four, without counting its metatarsal. The great toe has two, and the two succeeding toes three each. In all three the last is large, wide, and pointed to carry a claw. In the fourth and fifth toe this last phalanx is very small and without a claw.

In the Matamata (*Chelys*) the fourth toe is, like the two preceding, composed of three phalanges, and armed with a claw; the fifth also has three phalanges, and it would even have four if one regarded the bone as to which Cuvier has expressed his doubts as a tarsal bone; but the last is very small, cartilaginous, and without a nail. The tarsus is the same as in *Trionyx*, with this difference that the analogues of the astragalus and the calcaneum are divided transversely each into two bones; so that what is detached from the calcaneum forms a fourth cuneiform bone for the fourth metatarsal, and that which is detached from the astragalus is a true scaphoid, which carries the first three cuneiform bones.

Muscular System.—We have seen that the shoulder-blade is internal in the tortoises, that is, it is placed on the inside of the ribs; the muscles, consequently, of the head and neck, instead of being attached upon the ribs and spine, as in the other *Vertebrata*, are attached beneath them; the same observation holds as to the bones of the pelvis and the muscles of the thigh; so that, to use Cuvier's expression, a tortoise may be termed, in this respect, "un animal retourné"—an animal turned inside out, or rather, so to speak, outside in.

The progressive motions to be accomplished by the bony and muscular apparatus of the tortoises are those of walking and swimming or paddling.

The walk of a tortoise is proverbially slow, such as might be expected from a reptile whose limbs are so imperfectly developed. Short, and placed at a great distance from the centre, they form a sort of short crutches, calculated to drag the unwieldy body gradually along, and if the animal be turned on its back it becomes almost helpless. The feet are little better than stumps, the toes being only indicated externally by what may be termed a collection of hoofs, placed, as in the elephants, on the circumference of the apology for a foot, and which serve, so to speak, as a sort of grapplings to hold on the surface of the ground and drag the armed trunk onwards. We hardly need add that progression in a vertical direction is impossible; but many tortoises can burrow with some difficulty.

Nor is this slowness out of place: the preservation of the animal is provided for by the very strong bony carapace and plastron protecting the whole body, and only suffering the head, tail, and four feet to be protruded from its anterior and posterior part and its four angles; these protruded parts can be withdrawn into the shell upon the approach of danger, and the animal then rests secure in its portable arched castle, leaving the enemy to the hopeless task of besieging a garrison that can remain for months without food. A large Land-Tortoise can defy the whole animal world except man, from whom nothing is safe.

The most complete defence is made by the Box-Tortoises; for in them the pieces which form the sternum are moveable, and may be compared to doors or hinged lids, which shut upon the carapace and thus form a sort of closed coffer in which the head, neck, tail, and feet, in short, the only exposed parts, can at will be inclosed far more securely than a snail in its shell.

But this slowness is confined to the Terrestrial Tortoises; for the aquatic species swim with great facility on or below the surface; and some, *Chelone* and *Sphargis* for instance, with rapidity. But the well-developed flipper that enables the Marine Tortoise to oar its way with swiftness, is even a worse organ for land progression than the clumsy foot of a Land-Tortoise. Not but that they will shuffle back to the sea, which they have only occasion to leave in order to deposit their eggs, at a good pace, and they will deal heavy blows with their flippers to those who attempt to stop them (for they, as well as the Land-Tortoises, are very strong), as those who have been foiled in turning turtles, have known to their cost.

But however powerfully the muscles which act upon the head, tail, and extremities are developed in this order of reptiles, those of the abdomen, as might indeed be expected, have little extent, and those of the ribs, as might also be divined, are non-existent; for nature does nothing in vain: but the square muscle of the loins, whose principal office in mammals is to move the lumbar vertebræ, acts in the tortoises, which have those vertebræ fixed, in another direction, and is employed in drawing up the moveable os ilii; and the straight muscle (rectus abdominis) which extends from the pubis to the sternum, moves the whole haunch in the greater part of the *Testudinata*.

Digestive System.—The *Chelonia* have no teeth, although there are often a median groove and denticulated projections and hollows; but the mandibles are covered with a horny case, as in the birds. The *Chelydes* and the *Trionyces*, though they have the horny covering, have the mouth furnished with soft skin so as to form a kind of lips. The muscles that work the lower jaw, which is the only moveable one, are very powerful in many of the species; and the force with which the great Turtles and many other Chelonians grasp a solid body in their vice of a mouth is prodigious. The *Chelydes* are the only *Testudinata* which have the jaws flat and the gape of the mouth very wide.

The food with which the *Chelonia* have to deal is various, and there are modifications in the digestive organs accordingly. The *Chelones* and *Testudines* generally prefer a vegetable diet. The *Trionyces* and *Chelydes* prey upon fishes and small aquatic birds; and the *Emydes* attack the weaker animals, such as Crustaceans, Insects, Worms, and Mollusks.

These aliments are submitted in the Terrestrial Tortoises and in the Chelonians to the trenchant horny bill, well fitted to mince up vegetable fibre, assisted by the tongue, which draws the food into the mouth and the horny grooves and hollows of the jaws; the *Trionyces* and *Emydes* seize their living prey in their sharp-edged beaks and tear it to pieces with the cutting and pointed claws of their fore feet: some of these dart out their head and long neck upon their prey from an ambush; or, stealing along like the cats till they come within reach, suddenly extend their destructive apparatus with unerring aim. The *Chelydes*, whose fleshy jaws are flat, swallow their prey whole, and in this respect, as well as in the general conformation of the head and the os hyoides, they resemble the Toads, and especially the Pipas, like which they are obliged to be content with a victim of small dimensions suited to the calibre of their mouth, which is, in truth, sufficiently large. They are said never to seize their prey till they are satisfied by its motions that it is alive, for they never feed on carcasses.

The tongue of the tortoises is fleshy, like that of the parrots, and its nervous papillæ are very distinct. The œsophagus is short, and in the Chelonians is furnished internally with a number of close-set cartilaginous points, directed so as to prevent the regurgitation of the food towards the stomach, which has a transverse position. The intestines are long; the cloaca is situated beneath the tail, and rounded, and internally is found the orifice of canals which terminate in the cavity of the peritoneum. The liver is voluminous, forming two masses or lobes placed transversely below the heart and in front [illegible] the junction of the œsophagus with the stomach. The pancreas is [illegible] very large gland, and the spleen is rounded, median, and situated at a considerable distance from the liver. The chyle is translucid and aqueous in the vegetable feeders, but of a white and milky tint in those species which feed on animals.

The power of abstinence in this order of Reptiles is very great. Messrs. Duméril and Bibron state that they have seen a Long-Necked Emys remain more than a year without food; and Redi kept Land-Tortoises fasting for eighteen months.

Circulating System.—The heart in the *Chelonia* is composed of two auricles, and one ventricle with two unequal chambers which communicate together. The blood of the body enters into the right auricle and that of the lung into the left; but both these modifications of blood mingle more or less in passing by the ventricle.

Respiratory System.—Cuvier remarks that the quantity of respiration in Reptiles is not fixed, like that of Mammals and Birds, but varies with the proportion of the diameter of the pulmonary artery compared with that of the aorta. Thus, he observes, the Tortoises and the Lizards respire much more than the Frogs.

The lungs are of great extent, and placed in the same cavity with the abdominal viscera. We have seen that the thorax is immoveable, in the greater number at least, and the inlaid fixed ribs can give no assistance in respiration in the full-grown normal forms. It is therefore by the play of the parts about the mouth that the *Chelonia* respire, and here the complicated os hyoides is called into prominent action. The jaws are closed, and the animal alternately elevates and depresses the os hyoides; the first movement lets the air enter by the nostrils, and the tongue then closing their interior aperture, the second movement compels the air to penetrate into the lungs. In short, the Tortoises swallow or gulp down the air necessary for their respiration like Frogs.

John Hunter, in his 'MS. Catalogue,' observes that the vessels of the lungs of those animals whose whole blood passes through them are confined to the lungs, and lungs only, as distinctly as if the lungs were a separate animal; but this, he adds, is not the case with the *Amphibia*, "for," says he, "we find the vessels of the lungs of the Turtle communicate with those of other parts, such as the vessels of the œsophagus, which shows that the blood of that part is not so perfect in them as in others. From this it must appear that the lungs are not of that consequence in this class of animals that they are in the more perfect, for the lungs themselves appear to share in common with the other parts. Some of the blood which just came from the lungs returns back again to them, which would appear to answer no purpose; and on the other hand a considerable quantity of the blood which had undergone the general circulation (and therefore would appear to require refinement) just returns through the same course. It would appear from this admixture that it was not necessary that the whole of the blood should have undergone a thorough change for its greatest motion; yet we do not see why the lungs should have a part of their blood of the perfect kind. The cells of the lungs of the *Amphibia* seem to increase in size, the farther from the trunk or trachea, so that the trachea and its ramifications bear no proportion between them and the cells."

Brain, Nervous System, and Senses.—In the *Chelonia* generally, the vertical height of the capacity of the cranium is greater than in the other Reptiles; but in the Sea-Tortoises, or Turtles, the mass of the encephalon does not entirely fill it, and the highly vaulted bones are rather destined to serve as solid points of resistance to the upper beak, and to the powerful action of the muscles which act upon the lower jaw. The mass of the encephalon is less elongated and more compact than in the serpents. Bojanus, in his work on the 'Anatomy of the European Emys,' has shown that the great sympathetic or ganglionic series of nerves exists in that reptile nearly as it does in the other *Vertebrata*; that on the one hand it has sympathetic relations with the encephalic and vertebral nerves, and that on the other it makes a communication between the two lateral and symmetrical parts of the body, at the same time that its filaments are distributed and intermingle in numerous plexuses round the principal arteries destined to the nutrition of the internal viscera. Elaborate illustrations of the Nervous System, and especially of the great Sympathetic of the Hawk's-Bill Turtle, have been published by Mr. Swan, in his 'Comparative Anatomy of the Nerves,' 4to., 1836.

Here we must notice the experiments of Redi, which were perhaps more cruel in appearance than in reality. Most are familiar with the length of time that a turtle will move after its head is off, and the snap of the jaws which the severed head will give; but there is reason for believing that there is more of irritability than sensation in such motions; and the state of Redi's tortoises must have been analogous.

Redi, in the beginning of November, made a large opening in the skull of a Land-Tortoise, extracted the brain, and cleaned out the cavity. He then set the animal at liberty, and it groped its way freely about wherever it pleased, as if it had not been injured. Redi makes use of the term 'groping' (brancolando), because he says that when the tortoise was deprived of its brain it closed its eyes, which it never again opened. The wound which was left open skinned over in three days, and the tortoise, continuing to go about and execute other movements, lived to the middle of May. On a post-mortem examination the cavity which the brain had occupied was found em[illegible] and clean, with the exception of a small dry and black clot of bl[illegible] He repeated this experiment upon many other Land-Tortoises in the months of November, January, February, and March, with this difference, that some were locomotive at their pleasure, whilst others, though they made other motions, did not move about: he found the same results when he treated Fresh-Water Tortoises in the same manner, but they did not live so long as the terrestrial species. He states his belief that the Marine Tortoises would live a long time without their brain, for he received a turtle which he treated in the same way, and though it was much spent and faint from having been long out of the sea, it lived six days. In November he deprived a large tortoise of its head, without which it continued to live twenty-three days: it did not move about as those did whose brain had been taken out, but when its fore or hind legs were pricked or poked, it drew them up with great strength, and executed many other movements. To assure himself beyond all doubt that life, such as it was, continued in such cases, he cut off the heads of four other tortoises, and on opening two, twelve days afterwards, he saw the heart beat and the blood enter and leave it.

We have already had occasion to call attention to the great length of time during which these reptiles will live without food, and the facts above recorded afford additional proof of their extreme tenacity of life.

Touch.—In the greater part of this order, skin, properly so called, does not exist at all on certain parts of the body, or is reduced to a delicate fibrous plate applied like a simple periosteum on the bones of the head and on the external parts of the vertebræ of the back, the ribs, and sternum. The Soft Tortoises (*Trionyx* and *Sphargis*, for instance) are the only ones that differ in this respect. Nevertheless the neck, the feet, and most frequently a considerable part of the tail, are covered with a true flexible skin. This skin in the Matamata is fringed, or furnished with moveable appendages on the lateral parts of the head and neck. There can be no doubt that the sort of touch or sensation which will indicate to a *Trionyx*, or even to a Marine or Land-Tortoise, the differences of temperature that affect the medium wherein it mŏves, is present in those animals, but the sensibility of a true touch must be very much blunted in them. Some have their toes united down to the nails, or rather hoofs, and absolutely immoveable; others have them flattened, and forming a sort of paddle, as in *Chelone* and *Sphargis*; or the whole foot terminates by a sort of shapeless stump, rounded like the of the elephant, the presence of the toes being only indicated by those nails or hoofs, as in the Land-Tortoises. Others, it is true, *Emys*, *Trionyx*, and *Chelys*, for example, have their toes very distinct, but they are nevertheless united by membranes, and in general their feet seem more adapted for the different modes of transport than for touch. The Matamata indeed has its nose prolonged into a sort of moveable proboscis; but this organisation seems to be directed more to favour the required mode of respiration, than to give the animal that sort of perception exercised by the snout of swine and the muzzles of moles and some shrews. (Duméril and Bibron.)

Taste.—The wide fleshy tongue, with its distinct papillæ, like those of Mammals, seems well calculated for tasting vegetable and animal juices after the food is minced up by the horny mandibles; the fleshy lips on the outside of these mandibles in the *Trionyces* probably assist in retaining these juices.

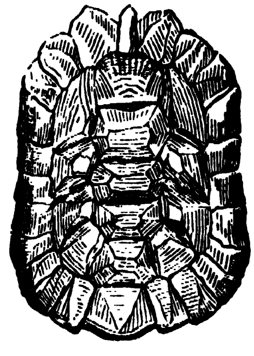
Smell.—Though there is probably sufficient of this sense to assist the animal in its discrimination of food, and aid the functions of the tongue in giving the animal a perception of flavour, it may be concluded from the very simple state of the organs, so different from the complication of those in animals where the sense is known to be highly developed, that it is not very acute in the tortoises.

Hearing.—From the structure of the internal ear, to which we have before alluded, it might be inferred that this function is tolerably acute, but many of the species appear very insensible to sound.

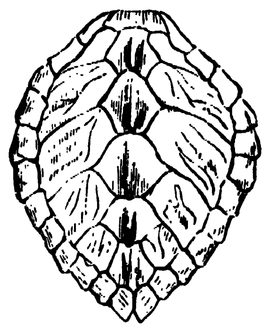
Sight.—The eye is well developed and is large. It is modified so as to be adapted to the medium, whether air or water, through which the light is to be transmitted. In the substance of the cornea scales or osseous plates are found analogous to those in birds, and there are three eyelids and two lachrymal glands.

Reproduction.—According to the accounts of voyagers the Coriaceous Tortoises (*Sphargis*) and the *Trionyces* seem to pair, and two individuals of different sexes remain constantly together in the same places. The great Marine Tortoises, as is well known, come every year at their appointed times to deposit their eggs in the sand on the shores of the sea and banks of rivers near strands of gentle declivity. There the females hollow out a sort of rude but strong vaulted nest or oven, as it may be termed, wherein the eggs may have the benefit of the concentrated rays of the sun, so as to enjoy an equable heat, as in the case of eggs under a sitting hen, but under circumstances which do not permit the body of the mother to impart the necessary warmth. The shell of these eggs is generally solid, and their form globular, or of a short cylindrical shape equally rounded at the extremities. A female Turtle will lay as many as a hundred at one time. The plastron of the males of many species of *Chelonia* is concave, that of the females being convex. Messrs. Duméril and Bibron say that in the Chelonians and Anourous Batrachians from eighteen to thirty-one days and more have elapsed before the male has quitted the female.

With regard to the integument of the carapace and plastron, the number, colour, and shape of the investing plates of horn or shell, as it is termed, vary considerably. The subjoined cuts will convey a better notion than words of their arrangement in a land and marine species; but it must be considered that these are mere examples, and that the variety is very great.



Carapace of *Testudo marginata*, covered with shell.



Carapace of *Chelone Caouana*, covered with shell.

Systematic Arrangement and Natural History.

Aristotle has mentioned three principal groups of Tortoises, or at any rate genera, under the names of Χελώη χερσαία for the Land-Tortoise; Χελώνη θαλαττία or θαλασσία for the Sea-Tortoise or Turtle ('Hist. Anim., ii. 17); and 'Εμύs for the Fresh-Water Tortoise (Ibid., v. 33). Gesner remarks that there are three "summa genera" of Tortoises: the 1st, terrestrial; the 2nd, living in fresh-waters; and the 3rd, in the waters of the sea. Messrs. Duméril and Bibron copy his 'Corallarium de Testudinibus in Genere,' to show how far it accords with their own arrangement, as follows:

Testudo aut est
- *terrestris*
- *aquatica*, aut in
  - mari
    - *Testudo marina*, Χελώνη θαλαττία.
    - *Mus marinus*, Μύs θαλάττιοs.
  - aquâ dulci
    - puriore, ut lacubus, amnibus.
    - cœnosâ, ut paludibus.

Linnæus placed the form at the head of his *Amphibia Reptilia*, under the generic name *Testudo*.

Cuvier divides them into five sub-genera:—1, the Land-Tortoises (*Testudo*, Brongn.); 2, the Fresh-Water Tortoises (*Emys*, Brongn.), including the Box-Tortoises (*Terrapene*, Merrem; *Kinosternon*, Spix; *Cistudo*, Fleming); 3, the Marine Tortoises; 4, the Chelydes (*Testudo fimbriata*); 5, the Soft Tortoises (*Trionyx*, Geoff.).

Dr. J. E. Gray, in his 'Catalogue of the Tortoises, Crocodiles, and Amphisbænians, in the Collection of the British Museum,' 1844, makes the *Chelonia*, the third order of Reptiles in his arrangement, come under his second section, *Cataphracta*, the *Squamata* being the first.

Family 1. *Testudinidæ.*

Genera:—*Testudo.* *Chersina.* *Kinixys.* *Pyxis.*

Family 2. *Emydidæ.*

Genera:—*Geoemyda.* *Emys.* *Cyclemys.* *Malaclemys.* *Cistudo.* *Kinosternon.* *Chelydra.* *Platysternum.*

Family 3. *Chelydidæ.*

Genera:—*Sternotherus.* *Pelomedusa.* *Hydraspis.* *Chelymys.* *Phrynops.* *Chelodina.* *Hydromedusa.* *Chelys.* *Peltocephalus.* *Podocnemis.*

Family 4. *Trionycidæ.*

Genera:—*Trionyx.* *Emyda.*

Family 5. *Cheloniadæ.*

Genera:—*Sphargis.* *Chelonia.* *Caretta.* *Caouana.*

Messrs. Duméril and Bibron, in their elaborate and highly valuable 'Erpétologie,' divide the Tortoises, or Chelonians, into the following families:—1st, the Chersites (Chersians, or Land-Tortoises); 2nd, the Elodites (Elodians, or Marsh-Tortoises); 3rd, the Potamites (Potamians, or River-Tortoises); 4th, the Thalassites (Thalassians, Sea-Tortoises, or Turtles).

Of these groups the authors observe that Chersites is not perfectly limited, for some of the species arranged by them under the succeeding family (Elodites) seem to form a natural passage between the Land- and Marsh-Tortoises. Such are *Cistudo Carolina* and *Emys Muhlenburgii*, which are in reality Paludines, or Marsh-Tortoises, with distinct toes, though they possess only very short membranes and but slightly palmated feet.

The principal characters which distinguish the Chersites, or Chersians, from the three other divisions of the order *Chelonia* are thus defined:—Body short, oval, convex, covered with a carapace and a plastron; four feet; no teeth. But Messrs. Duméril and Bibron remark that the principal distinction may be enunciated by this simple term drawn from the conformation of the limbs, and which indicates perfectly the manner of life of the group—stumpy feet (des pattes en moignon):—this would recall the condition of those feet, namely, that they are short, unshapely, though nearly of equal length, with toes but little distinct, nearly equal, immoveable, united by a thick skin, and conglomerated into a sort of truncated mass, callous in its periphery, on the outside of which one only distinguishes horny cases, a sort of hoofs which for the most part correspond with the last phalanges they incase, and would consequently show that these animals live only on the land, never in the water. The other three groups differ from the last and from each other in the form of the feet.

The Thalassites, or Thalassians, have the carapace very much depressed, and their two pairs of feet, unequal in length, are flattened into the form of oars or solid fins, because their toes are always conjoined and hardly distinct from each other, incased as they are in these paddles.

The Elodites, or Elodians, have the toes separate, or rather separately moveable, furnished with crooked claws, most frequently palmated or united at their base by membranes, as in the Duck Tribe among birds; but the transition of these last three families is, so to speak, insensible on the one side between the species of the genus *Cistudo*, and on the other between *Chelys* and all the species generally known as Soft Tortoises.

These last, the Potamites, or Potamians, have also the toes palmated or connected by membranes; they have pointed claws, three in number only, on each foot; their pointed and trenchant beak is constantly furnished externally with folds of the skin, like lips, appendages which have hitherto been only observed in this family. In addition their bony carapace is covered with a coriaceous skin, the edges of which in the greater number remain flexible and floating on the sides of the body.

Family 1. Chersians—Land-Tortoises.

				Genera.
Carapace	Moveable behind, where it is, as it were, articulated			4, *Kinixys.*
	Immoveable; nails on the anterior feet	four only		2, *Homopus.*
		five, front of the plastron	moveable	3, *Pyxis.*
			immoveable	1, *Testudo.*

Testudo.—Feet with five toes, hind-feet with four nails only; carapace of a single piece; sternum not moveable anteriorly.

This genus is divided by Messrs. Duméril and Bibron into three sections or sub-genera:—

1. Those species which have the posterior portion of their plastron moveable. These correspond with the genera *Chersus* of Wagler; *Testudo* of authors; *Chersina* of Gray.

2. Those species whose plastron is solid in all its parts, or of a single piece covered with twelve plates.

3. Those species which have the sternum equally immoveable, but covered with eleven horny plates.

These sections embrace twenty-two species.

In the first section *Testudo marginata*, Schœpf., and *T. Mauritianica*, Dum. and Bibr., are placed.

In the second are *Testudo Græca*, Linn.; *T. geometrica*, Linn.; *T. actinodes*, Bell; *T. pardalis*, Bell; *T. sulcata*, Miller; *T. nigrita*, Dum. and Bibr.; *T. radiata*, Shaw; *T. tabulata*, Walbaum; *T. carbonaria*, Spix; *T. polyphemus*, Daud.; *T. Schweiggeri*, Gray; *T. elephantina*, Dum. and Bibr.; *T. nigra*, Quoy and Gaim.; *T. gigantea*, Schweigg.; *T. Daudinii*, Dum. and Bibr.; *T. Perraultii*, Dum. and Bibr.

In the third are *T. angulata*, Dum. and Bibr.; *T. Graii*, Dum. and Bibr.; *T. peltastes*, Dum. and Bibr.; and *T. Vosmaeri*, Fitzing.

For an account of the habits of Land-Tortoises we turn to the records of two acute and eloquent observers, whose narratives it would be unjust to give in other words than their own.

White of Selborne thus writes to the Honourable Daines Barrington, in April, 1772:—"While I was in Sussex last autumn, my residence was at the village near Lewes, whence I had formerly the pleasure of writing to you. On the 1st of November I remarked that the old tortoise formerly mentioned began first to dig the ground in order to the forming its hybernaculum, which it had fixed on just beside a great tuft of hepaticas. It scrapes out the ground with its fore feet, and throws it up over its back with its hind feet; but the motion of its legs is ridiculously slow, little exceeding the hour-hand of a clock. . . . Nothing can be more assiduous than this creature night and day in scooping the earth and forcing its great body into the cavity; but as the noons of that season proved unusually warm and sunny, it was continually interrupted, and called forth by the heat in the middle of the day; and though I continued there till the 13th of November, yet the work remained unfinished. Harsher weather and frosty mornings would have quickened its operations. No part of its behaviour ever struck me more than the extreme timidity it always expresses with regard to rain; and though it has a shell that would secure it against a loaded cart, yet does it discover as much solicitude about rain as a lady dressed in all her best attire, shuffling away on the first sprinklings, and running its head up in a corner. If attended to, it becomes an excellent weather-glass; for as sure as it walks elate, and as it were on tiptoe, feeding with great earnestness in the morning, so sure will it rain before night. It is totally a diurnal animal, and never pretends to stir after it becomes dark. The tortoise, like other reptiles, has an arbitrary stomach as well as lungs, and can refrain from eating as well as breathing for a great part of the year. When first awakened it eats nothing; nor again in the autumn before it retires: through the height of the summer it feeds voraciously, devouring all the food that comes in its way. I was much taken with its sagacity in discerning those that do it kind offices; for as soon as the good old lady comes in sight who has waited on it for more than thirty years, it hobbles towards its benefactress with awkward alacrity, but remains inattentive to strangers. Thus, not only 'the ox knoweth his owner, and the ass his master's crib,' but the most abject reptile and torpid of beings distinguishes the hand that feeds it, and is touched with the feelings of gratitude." In a postscript he adds, that in about three days after he left Sussex the tortoise retired into the ground under the hepaticas.

In April, 1780, White again writes to Mr. Barrington:—"The old tortoise that I have so often mentioned to you is become my property. I dug it out of its winter dormitory in March last, when it was enough awakened to express its resentment by hissing; and, packing it in a box with earth, carried it eighty miles in post-chaises. The rattle and hurry of the journey so perfectly roused it, that when I turned it out on a border, it walked twice down to the bottom of my garden; however, in the evening, the weather being cold, it buried itself in the loose mould, and continues still concealed. As it will be under my eye, I shall now have an opportunity of enlarging my observations on its mode of life and propensities, and perceive already that, towards the time of coming forth, it opens a breathing-place in the ground near its head, requiring, I conclude, a freer respiration as it becomes more alive. This creature not only goes under the earth from the middle of November to the middle of April, but sleeps great part of the summer; for it goes to bed in the longest days at four in the afternoon, and often does not stir in the morning till late. Besides, it retires to rest for every shower, and does not move at all in wet days. When one reflects on the state of this strange being, it is a matter of wonder to find that Providence should bestow such a profusion of days, such a seeming waste of longevity, on a reptile that appears to relish it so little as to squander more than two-thirds of its existence in a joyless stupor, and be lost to all sensation for months together in the profoundest of slumbers.

"While I was writing this letter a moist and warm afternoon, with the thermometer at 50°, brought forth troops of shell-snails; and, at the same juncture, the tortoise heaved up the mould and put out its head; and the next morning came forth, as it were raised from the dead, and walked about till four in the afternoon. This was a curious coincidence—a very amusing occurrence—to see such a similarity of feeling between the two *φερέοικοι*—for so the Greeks call the shell-snail and the tortoise."

Again White reverts to the "old family tortoise" in the same letter:—"Because we call this creature an abject reptile, we are too apt to undervalue his abilities and depreciate his powers of instinct. Yet he is, as Mr. Pope says of his lord,

'much too wise to walk into a well;'

and has so much discernment as not to fall down an haha, but to stop and withdraw from the brink with the readiest precaution. Though he loves warm weather, he avoids the hot sun, because his thick shell, when once heated, would, as the poet says of solid armour, 'scald with safety.' He therefore spends the more sultry hours under the umbrella of a large cabbage-leaf, or amidst the waving forests of an asparagus-bed. But as he avoids heat in the summer, so, in the decline of the year, he improves the faint autumnal beams by getting within the reflection of a fruit-wall; and though he never has read that planes inclining to the horizon receive a greater share of warmth, he inclines his shell by tilting it against the wall, to collect and admit every feeble ray. Pitiable seems the condition of this poor embarrassed reptile: to be cased in a suit of ponderous armour which he cannot lay aside; to be imprisoned, as it were, within his own shell, must preclude, we should suppose, all activity and disposition for enterprise. Yet there is a season of the year (usually the beginning of June) when his exertions are remarkable. He then walks on tiptoe, and is stirring by five in the morning; and, traversing the garden, explores every wicket and interstice in the fences, through which he will escape, if possible; and often has eluded the care of the gardener, and wandered to some distant field. The motives that impel him to undertake these rambles seem to be of the amorous kind; his fancy then becomes intent on sexual attachments, which transport him beyond his usual gravity, and induce him to forget for a time his ordinary solemn deportment."

Mr. Darwin in his 'Journal' describes the habits of *Testudo Indica*, or rather one of the species that have been confounded under that name, and, not improbably, the *Testudo nigra* of Quoy and Gaimard. He speaks of their numbers as being very great, as indeed they always seem to have been, for he quotes Dampier, who states that they are so numerous that five or six hundred men might subsist on them for several months without any other sort of provisions, and describes them as being so extraordinarily large and fat that no pullet eats more pleasantly. The day on which Mr. Darwin visited the little craters in the Galapagos Archipelago was glowing hot, and the scrambling over the rough surface and through the intricate thickets was very fatiguing. "But," says Mr. Darwin, "I was well repaid by the Cyclopian scene. In my walk I met two large tortoises, each of which must have weighed at least two hundred pounds. One was eating a piece of cactus, and when I approached it looked at me, and then quietly walked away; the other gave a deep hiss and drew in his head. These huge reptiles, surrounded by the black lava, the leafless shrubs, and large cacti, appeared to my fancy like some antediluvian animals."

Mr. Darwin states his belief that these tortoises are found in all the islands of the Archipelago; certainly in the greater number, and thus continues his description:—"They frequent, in preference, the high damp parts, but likewise inhabit the lower and arid districts. Some individuals grow to an immense size. Mr. Lawson, an Englishman, who had, at the time of our visit, charge of the colony, told us that he had seen several so large that it required six or eight men to lift them from the ground, and that some had afforded as much as two hundred pounds of meat. The old males are the largest, the females rarely growing to so great a size. The male can readily be distinguished from the female by the greater length of its tail. The tortoises which live on those islands where there is no water, or in the lower and arid parts of the others, chiefly feed on the succulent cactus. Those which frequent the higher and damp regions eat the leaves of various trees, a kind of berry (called guayavita) which is acid and austere, and likewise a pale green filamentous lichen, that hangs in tresses from the boughs of the trees.

"The tortoise is very fond of water, drinking large quantities, and wallowing in the mud. The larger islands alone possess springs, and these are always situated towards the central parts, and at a considerable elevation. The tortoises, therefore, which frequent the lower districts, when thirsty are obliged to travel from a long distance. Hence, broad and well-beaten paths radiate off in every direction from the wells even down to the sea-coast; and the Spaniards, by following them up, first discovered the watering-places. When I landed at Chatham Island, I could not imagine what animal travelled so methodically along the well-chosen tracks. Near the springs it was a curious spectacle to behold many of these great monsters; one set eagerly travelling onwards with outstretched necks, and another set returning, after having drunk their fill. When the tortoise arrives at the spring, quite regardless of any spectator, it buries its head in the water above its eyes, and greedily swallows great mouthfuls, at the rate of about ten in a minute. The inhabitants say that each animal stays three or four days in the neighbourhood of the water, and then returns to the lower country; but they differed in their accounts respecting the frequency of these visits. The animal probably regulates them according to the nature of the food which it has consumed. It is however certain that tortoises can subsist even on those islands where there is no other water than what falls during a few rainy days in the year.

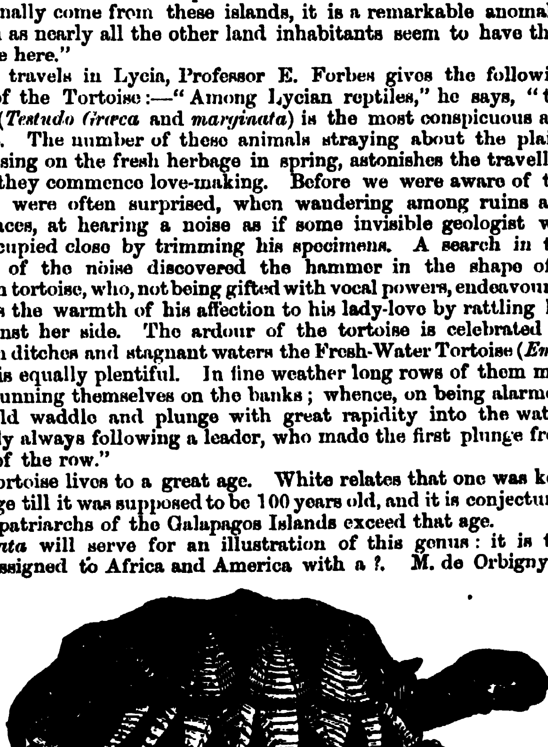
"I believe it is well ascertained that the bladder of the frog acts as a reservoir for the moisture necessary to its existence: such seems to be the case with the tortoise. For some time after a visit to the springs, the urinary bladder of these animals is distended with fluid, which is said gradually to decrease in volume and to become less pure. The inhabitants, when walking in the lower district, and overcome with thirst, often take advantage of this circumstance, by killing a tortoise, and if the bladder is full, drinking its contents. In one I saw killed, the fluid was quite limpid, and had only a very slightly bitter taste. The inhabitants however always drink first the water in the pericardium, which is described as being best. The tortoises, when moving towards any definite point, travel by night and by day, and arrive at their journey's end much sooner than would be expected. The inhabitants, from observations on marked individuals, consider that they can move a distance of about eight miles in two or three days. One large tortoise which I watched, I found walked at the rate of 60 yards in 10 minutes, that is, 360 yards in the hour, or four miles a day—allowing also a little time for it to eat on the road. During the breeding season, when the male and female are together, the male utters a hoarse roar or bellowing, which, it is said, can be heard at the distance of more than 100 yards. The female never uses her voice, and the male only at such times; so that when the people hear this noise, they know the two are together. They were at this time (October) laying their eggs. The female, where the soil is sandy, deposits them together, and covers them up with sand; but where the ground is rocky, she drops them indiscriminately in any hollow. Mr. Bynoe found seven placed in a line in a fissure. The egg is white and spherical; one which I measured was 7⅜ inches in circumference. The young animals, as soon as they are hatched, fall a prey in great numbers to the buzzard with the habits of the caracara. The old ones seem generally to die from accidents, as from falling down precipices. At least several of the inhabitants told me they had never found one dead without some such apparent cause. The inhabitants believe that these animals are absolutely deaf; certainly they do not overhear a person walking close behind them. I was always amused, when overtaking one of these great monsters as it was quietly pacing along, to see how suddenly, the instant I passed, it would draw in its head and legs, and uttering a deep hiss fall to the ground with a heavy sound, as if struck dead. I frequently got on their backs, and then, upon giving a few raps on the hinder part of the shell, they would rise up and walk away; but I found it very difficult to keep my balance. The flesh of this animal is largely employed, both fresh and salted; and a beautifully clear oil is prepared from the fat. When a tortoise is caught, the man makes a slit in the skin near its tail, so as to see inside its body, whether the fat under the dorsal plate is thick. If it is not, the animal is liberated; and it is said to recover soon from this strange operation. In order to secure the tortoises, it is not sufficient to turn them like turtle, for they are often able to regain their upright position.

"It was confidently asserted that the tortoises coming from different islands in the Archipelago were slightly different in form; and that in certain islands they attained a larger average size than in others. Mr. Lawson maintained that he could at once tell from which island any one was brought. Unfortunately, the specimens which came home in the 'Beagle' were too small to institute any certain comparison. This tortoise, which goes by the name of *Testudo Indica*, is at present found in many parts of the world. It is the opinion of Mr. Bell, and some others who have studied reptiles, that it is not improbable that they all originally came from this Archipelago. When it is known how long these islands have been frequented by the buccaniers, and that they constantly took away numbers of these animals alive, it seems very probable that they should have distributed them in different parts of the world. If this tortoise does not originally come from these islands, it is a remarkable anomaly; inasmuch as nearly all the other land inhabitants seem to have their birthplace here."

In his travels in Lycia, Professor E. Forbes gives the following account of the Tortoise:—"Among Lycian reptiles," he says, "the Tortoise (*Testudo Græca* and *marginata*) is the most conspicuous and abundant. The number of these animals straying about the plains and browsing on the fresh herbage in spring, astonishes the traveller. In April they commence love-making. Before we were aware of the cause, we were often surprised, when wandering among ruins and waste places, at hearing a noise as if some invisible geologist was busily occupied close by trimming his specimens. A search in the direction of the noise discovered the hammer in the shape of a gentleman tortoise, who, not being gifted with vocal powers, endeavoured to express the warmth of his affection to his lady-love by rattling his shell against her side. The ardour of the tortoise is celebrated by Ælian. In ditches and stagnant waters the Fresh-Water Tortoise (*Emys Caspica*) is equally plentiful. In fine weather long rows of them may be seen sunning themselves on the banks; whence, on being alarmed, they would waddle and plunge with great rapidity into the water, apparently always following a leader, who made the first plunge from one end of the row."

The Tortoise lives to a great age. White relates that one was kept in a village till it was supposed to be 100 years old, and it is conjectured that the patriarchs of the Galapagos Islands exceed that age.

T. sulcata will serve for an illustration of this genus: it is the species assigned to Africa and America with a ?. M. de Orbigny is stated to have himself collected the young of *Testudo sulcata* in Patagonia, where, according to him, the species is very common. Messrs. Duméril and Bibron declare that other specimens come without doubt from Africa.



Testudo sulcata.

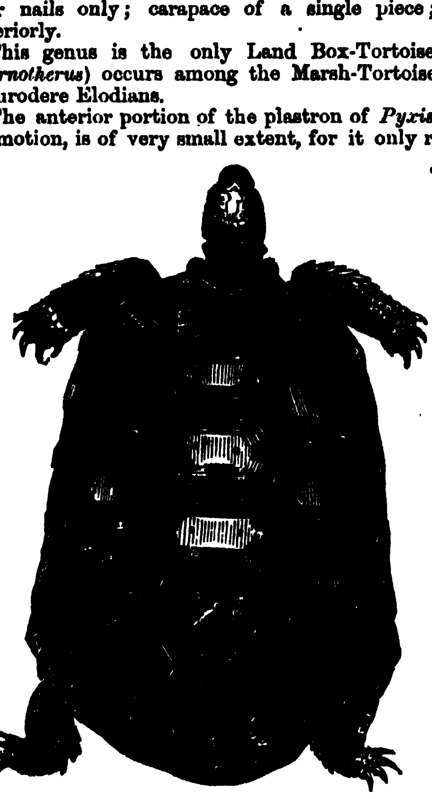
Homopus, Dum. and Bibr.—Four toes only on each foot, and all unguiculate; carapace and sternum of a single piece. There are two species:—

H. areolatus; H. signatus.

Pyxis, Bell.—Feet each with five toes, the posterior ones with four nails only; carapace of a single piece; sternum moveable anteriorly.

This genus is the only Land Box-Tortoise; but an analogue (*Sternotherus*) occurs among the Marsh-Tortoises, in the division of Pleurodere Elodians.

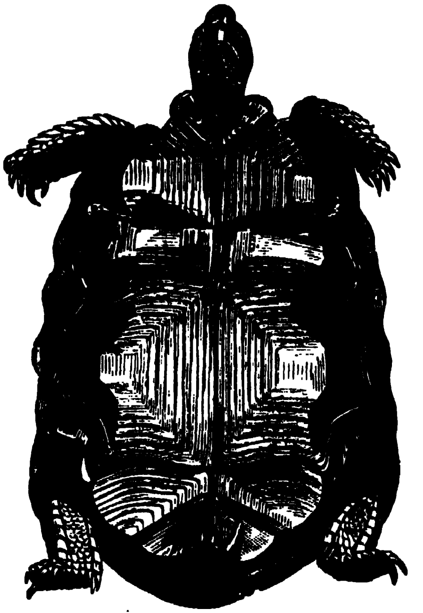
The anterior portion of the plastron of *Pyxis*, which is susceptible of motion, is of very small extent, for it only reaches, backwards, to the space of the first two pairs of sternal plates, and consequently it is under the strongly indicated suture of the second with the third pair that the elastic ligament which performs the office of a hinge is seen. By means of this sort of moveable door or lid, the *Pyxis* can, by lowering it at will, protrude its head and its fore feet, and by raising it, shut itself up in a sort of box, for the edges of this hinged operculum closely fit those of the carapace, which serve it as a door-case. The animal then has nothing to fear, because its sternum protects behind, by its enlargement, the space by which the feet and the tail can be put forth and deeply drawn up.



Pyxis arachnoides, seen from above.

P. arachnoides is the only species known.

Kinixys, Bell.—Feet with five toes, the posterior ones with four nails only; carapace moveable behind; sternum of a single piece.



Pyxis arachnoides, seen from below.

Messrs. Duméril and Bibron observe that this is the most curious of the family Chersites. The Chelonians that compose it alone enjoy the faculty of moving the posterior part of their carapace in order to lower it and apply it against the plastron, so as completely to close the osseous box behind, as the *Pyxides* close theirs before when they elevate the moveable anterior portion of their plastron. But, as we have seen, the mobility of the anterior part of the sternum is in *Pyxis* due to the presence of an elastic ligament which performs the office of a hinge, whilst in *Kinixys* the carapace offers no really moveable articulation; the bones, the vertebræ, and ribs are the parts which bend. In consequence of this elasticity of the bones and their thinness, the carapace can be moved down to approximate the sternum. The sinuous line on which this flexion operates is indicated externally by a slight space, which is filled by a sort of fibro-cartilaginous tissue. This undulated line exists between the antepenultimate and the penultimate margino-lateral plate.

The three known species have not, like all the other Chersians, the abdominal plates much more extensive than the other horny plates of the sternum, which, joined to the enlargement and the rounded contour of the plastron behind, approximates them in a certain degree to *Cistudo*, the first genus of the Elodians. There are three species:—

K. Homeana; K. erosa; K. Belliana.

Pausanias notices a Land-Tortoise in the woods of Arcadia, whose shell was used to make lyres.

Family II. Elodians—Marsh-Tortoises.

The habits of the Elodians differ very much from those of the other three great groups of Chelonians. The Marsh-Tortoises have not the slowness of the Land-Tortoises. They swim with facility, and on land make much quicker progress than the Chersians. They frequent small streams whose course is not too rapid, lakes, ponds, and marshes: they are not almost entirely vegetable-feeders, like the Chersians and Thalassians, but, like the Potamians, prey on living animals; river-mollusks, Anourous and Urodele Batrachians, and Annelides are their food.

The eggs are generally spherical, with a calcareous shell, and white, like those of the other Chelonians. The females deposit them in shallow cavities, which they hollow out in the earth, nearly in the same manner as the Land-Tortoises; but the Elodians prefer the banks of the waters where they dwell, in order that their young ones may the more easily there find refuge from their numerous enemies. The number of eggs varies according to the species, and probably according to the age of the individuals, for the females are capable of producing fertile eggs for some years before they have attained their full growth.

Sub-Family 1.—Cryptodere Elodians.

Cryptoderes are not only distinguished from the Pleuroderes by the power of completely concealing their cylindrical neck with its sheath of loose skin under the middle of the carapace; but also by their head, which is nearly equal in width to its height at the occiput. The eyes are always lateral, and their orbits so large that the diameter of the cavity nearly equals a fourth of the total extent of the cranium considered with regard to its length. The jaws of the Cryptoderes are stronger than those of the Pleuroderes; sometimes they are simply trenchant, sometimes more or less dentilated on their edges, which are straight, or sometimes sinuous. In the greater number of species the anterior extremity of the upper beak offers a large notch, on each side of which may be seen pretty constantly a rather strong tooth; in which case it is rare for the corresponding extremity of the mandible not to curve upwards towards the muzzle in a sharp point. In short, in such cases the upper beak closely resembles that of birds of prey.

Sub-Genus 1.—The Clausiles.

Cistudo, Fleming, reformed by Gray.—Feet with five toes, the posterior with four claws only; plastron wide, oval, attached to the buckler by a cartilage, moveable before and behind on the same transversal mesial hinge, furnished with twelve plates; twenty-five marginal horny plates or scales.

C. Carolina; C. Amboinensis; C. trifasciata.

Sub-Genus 2.—The Gapers.

C. Europæa and *C. Diardii.*

Emys, Dum. and Bibr.—Feet with five toes, the posterior with four nails only; plastron wide, immoveable, solidly articulated upon the carapace, furnished with twelve plates; two axillary and two inguinal shells; head of ordinary size; tail long.

1st Group.—European *Emydes*.

E. Caspica; E. Sigritz.

2nd Group.—American *Emydes*.

E. punctularia, E. marmorea, E. pulchella, E. geographica, E. concentrica, E. serrata, E. Dorbignii, E. irrigata, E. decussata, E. rubriventris, E. rugosa, E. Floridana, E. ornata, E. concinna, E. reticulata, E. guttata, E. picta, E. Bellii, and *E. Muhlenbergii.*

3rd Group.—African *Emys*.

E. Spengleri.

4th Group.—Oriental *Emydes*.

E. Trijuga, E. Reevesii, E. Hamiltonii, E. Thurjii, E. tecta, E. Bealei, E. crassicollis, E. spinosa, E. ocellata, E. trivittata, E. Duvaucellii, and *E. lineata.*

Tetraonyx, Lesson.—Five toes, one of them without a nail on all the feet; sternum solid, wide, furnished with six pairs of plates; twenty-five marginal scales.

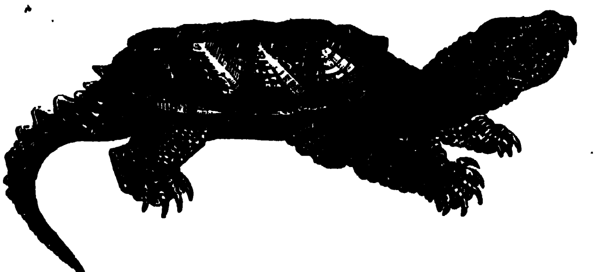
T. Lessonii; T. Baska.

Platysternon, Gray.—Head armed or shielded, and too large to enter under the carapace; upper jaw hooked; sternum wide, immoveable, fixed solidly to the carapace, with short alæ; three sterno-costal scales; five nails on the anterior feet; four only on the posterior feet; tail very long, scaly, without a crest.

P. megacephalum.

Emysaura, Dum. and Bibr.—Head large, covered with small plates; muzzle short; two barbles under the chin; plastron immoveable, cruciform, covered with twleve plates; three sterno-costal scales; five nails on the fore feet, four on the hind feet; tail long, surmounted by a scaly crest.

E. serpentina. It lives in lakes and rivers, feeding on fish, and, as it would seem, on young birds. This is *Testudo serpentina*, Linn.; *Chelydra serpentina*, Schweigg., and *Chelonura serpentina*, Say, &c.



Emysaura serpentina.

Staurotypus, Wagler.—Head sub-quadrangular, pyramidal, covered in front with a single very delicate scale only; jaws more or less hooked; barbles under the chin; twenty-three limbar scales; sternum thick, cruciform, moveable in front, furnished with eight or eleven scales; axillary and inguinal scales contiguous, placed on the sterno-costal sutures; anterior feet with five nails; posterior feet with four only.

S. triporcatus; S. odoratus, so called from the musky odour which it is said to exhale.

Kinosternon, Wagler.—Head sub-quadrangular, pyramidal; a single rhomboidal plate upon the cranium; jaws slightly hooked; barbles under the chin; scales of the shell slightly imbricated; limbar plates to the number of twenty-three; sternum oval, moveable before and behind on a fixed piece, furnished with eleven scales; alæ short, narrow, sub-horizontal; a very large axillary plate and an inguinal still larger; tail long (in the males), unguiculate.

K. scorpioides. It lives in marshes and on river-banks. *K. Pennsylvanicum* lives in muddy waters, feeding on small aquatic animals, and exhaling a strong musky odour. *K. hirtipes.*

Sub-Family 2.—Pleurodere Elodians.

The Pleuroderes, as their name indicates, have all of them the neck retractile upon one of the sides of the anterior aperture of the carapace; but they are never able completely to draw it in between their fore feet and under the middle of the buckler and plastron, like the Cryptoderes.

Peltocephalus, Dum. and Bibr.—Head large, sub-quadrangular, pyramidal, covered with large, thick, slightly imbricated plates; jaws extremely strong, hooked, without dentilations; eyes lateral; plates of the carapace slightly imbricated; no nuchal plate; feet slightly palmated: two large rounded scales at the heels; nails straight, robust; tail unguiculate.

P. Tracaxa.

Podocnemis, Wagler.—Head slightly depressed, covered with plates; front hollowed with a large longitudinal furrow; jaws slightly arched, without dentilations; two barbles under the chin; no nuchal plate; sternum wide, immoveable; feet largely palmated, the posterior ones carrying at the heels two large but delicate rounded scales; tail short, not unguiculate.

P. expansa. It lives in streams and rivers. *P. Dumeriliana.*

Pentonyx, Dum. and Bib.—Head large, depressed, covered with plates; muzzle rounded; jaws slightly arched, trenchant; two barbles under the chin; no nuchal plate; sternum immoveable; five claws on all the feet; tail moderate, not unguiculate.

P. Capensis; P. Adansonii.

Sternotherus, Bell.—Head depressed, furnished with great plates; jaws without dentilations; no nuchal plate; sternum wide, with very narrow lateral prolongations; free anterior portion of the plastron rounded, moveable: five claws on each foot.

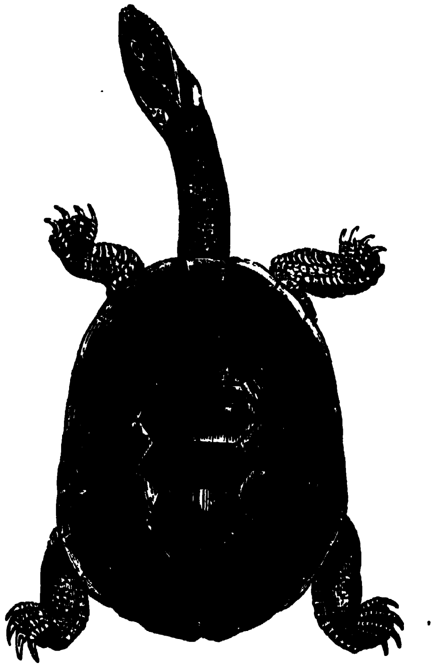
S. niger; S. nigricans; S. castaneus.

Platemys, Wagler, as reformed by Messrs. Duméril and Bibron, comprising part of *Hydraspis* of Gray, *Platemys*, *Rhinemys*, and *Phrynops* of Wagler.—Head flattened, covered with a single delicate scale or with a great number of small irregular plates; jaws simple; two barbles under the chin; carapace very much depressed; sternum immoveable; five claws on the fore feet, four on the hind.

It embraces the following species:—*P. Martinella* (Brazil and Cayenne); *P. Spixii* (Brazil); *P. radiolata* (Brazil, where it lives in the marshes); *P. gibba; P. Geoffreana* (young sent from Buenos Ayres by M. d'Orbigny); *P. Waglerii* (Brazil); *P. Nieuwiedii* (Brazil); *P. Gaudichaudii* (Brazil); *P. Hilarii* (Brazil); *P. Miliusii* (Cayenne); *P. rufipes* (Brazil, banks of the River Solimoens); *P. Schweiggerii* (South America); *P. Macquaria* (Macquarie River, Australia).

Chelodina, Fitzinger.—Head very long and very flat, covered with delicate skin; muzzle short, gape wide, jaws feeble, without dentilations; no barbles to the chin; neck very much elongated; a nuchal plate, plastron immoveable, very wide, rounded in front and solidly fixed on the carapace; sternal alæ very short; intergular scale larger than each of the gulars; four claws on each foot; tail excessively short.

C. Novæ Hollandiæ; C. flavilabris; C. Maximiliani.

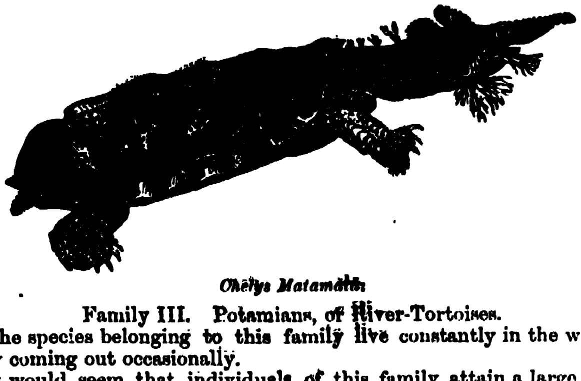


Chelodina Novæ Hollandiæ.

Chelys, Dum. and Bibr.—Head much depressed, wide, and triangular; nostrils prolonged into a proboscis; gape wide, jaws rounded, of but little thickness; neck furnished with long cutaneous appendages, two barbles to the chin; a nuchal plate; five claws on the fore feet, four on the hind feet.

The gape extends beyond the ears. Messrs. Duméril and Bibron remark that the jaws are rounded, narrow, and not simply covered with soft skin, as Cuvier, Wagler, and Gray believed, but protected by horny cases, like those of all the other Chelonians; only in *Chelys* they are extremely delicate.

C. Matamata. It lives in stagnant waters. A female lived some months at Paris and laid three eggs, one of which was hatched and the young animal preserved in the Paris Museum.



Chelys Matamata.

Family III. Potamians, or River-Tortoises.

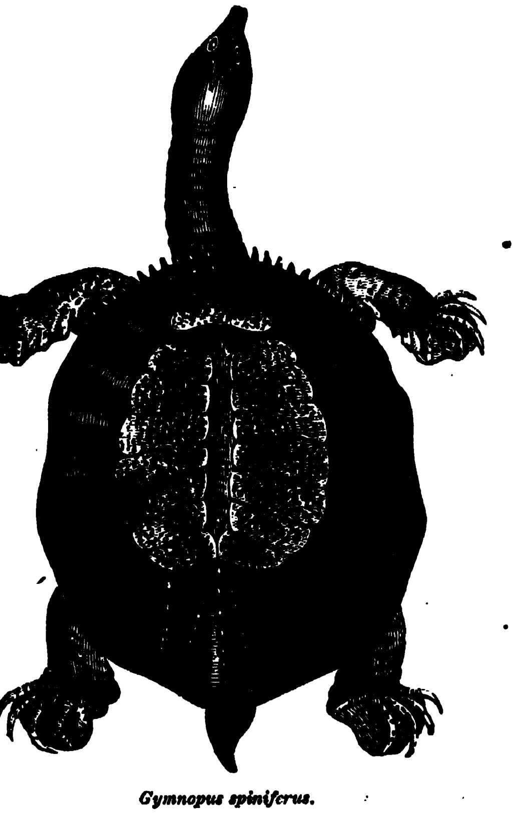
The species belonging to this family live constantly in the water, only coming out occasionally.

It would seem that individuals of this family attain a large size. Messrs. Duméril and Bibron quote Pennant as mentioning some which weighed 70lbs.; one which he kept three months weighed 20lbs., and its buckler was 20 inches in length, not reckoning the neck, which measured 13½ inches. Their mode of life and habits seem to have great similarity. They swim with much ease both on the surface and at mid-water. The lower part of their body is generally pale white, rosy, or bluish; but their upper parts vary in their tints, which are most frequently brown or gray, with irregularly marbled, dotted, or ocellated spots. Straight or sinuous brown, black, or yellow lines are disposed symmetrically on the right and left, principally on the lateral parts of the neck and on the limbs. During the nights, and when they believe themselves to be secure from danger, the Potamians come to repose on the islets, the rocks, the fallen trunks of trees upon the banks, or floating timber, whence they precipitate themselves in the water at the sight of man or at the least alarming noise. They are very voracious and agile, and pursue, as they swim, reptiles, especially young crocodiles and fishes. Their flesh being esteemed they are angled for with a hook and line baited with small fish or living animals, or with a dead bait, to which the angler gives motion and apparent life; for they are said never to approach a dead or immoveable prey. When they would seize their food or defend themselves they dart out their head and long neck with the rapidity of an arrow. They bite sharp with their trenchant beak, and do not let go till they have taken the piece seized out; so that their bite is much dreaded, and the fishermen generally cut off their heads as soon as they have caught them.

The males appear to be fewer in number than the females, or at least they come less frequently to the banks of rivers, where the females resort to deposit their eggs in hollows, which contain from fifty to sixty. The number varies according to the age of the females, which are less fruitful in proportion to their youth. The eggs are spherical, their shell is solid, but membranous or slightly calcareous.

Gymnopus, Dum. and Bibr. (*Trionyx*, Geoff.; *Aspidonectes*, Wagler). Carapace with a cartilaginous circumference, very large, floating behind, and deprived of bone externally; sternum too narrow behind to hide the limbs completely when the animal draws them up under the carapace. *Trionyx* and *Testudo ferox* of authors.

G. spiniferus. M. Lesueur states that towards the end of April, or most frequently in May, the females of this species seek out on the river banks sandy spots for the deposit of their eggs; steeps of ten or fifteen feet elevation deter them not when they are choosing places exposed to the sun. Their eggs are spherical, and their shell is more fragile than that of the eggs of the species of Elodians living in the same waters; their eggs amount to from fifty to sixty. M. Lesueur counted in the ovary twenty ready for laying, and a great quantity of others of variable dimensions, from that of a pin's head to the much greater volume which they attain when they are covered with their calcareous coat. The retreats of these tortoises are on rocks and on the trunks of trees overthrown in the river. They may be taken with hook and line baited with a little fish; they are very voracious, and bite their captors, so that the prudent cut off their heads. M. Lesueur was often bitten by those he had: they dart out their heads like lightning. The young begin to show themselves in July. The flesh of this species is very delicate.



Gymnopus spiniferus.

G. muticus (*Trionyx muticus*, Lesueur, Leconte, and Gray).

G. Ægyptiacus (*Trionyx Ægyptiacus*, Geoff.; *T. Niloticus*, Gray). This is supposed to be the Ἐμύς of Aristotle ('De Part. Anim.,' v. 9).

G. Duvaucelii (*Trionyx Gangeticus*, Cuv.; *T. Hurum*, Gray); *G. ocellatus* (*Trionyx ocellatus*, Hardwick; *T. Hurum*, the young, Gray); *G. lineatus* (*Trionyx Ægyptiacus*, var., Hardw.; *T. Indicus*, Gray); *G. Javanicus* (*Trionyx Javanicus*, Schweigg.); *G. subplanus* (*Trionyx subplanus*, Geoff.); *G. Euphraticus* (*Trionyx Euphraticus*, Geoff.).

Cryptopus, Dum. and Bibr. (*Trionyx*, Wagl.; *Emyda*, Gray).—Carapace with narrow cartilaginous borders supporting above the neck and behind the thighs small bony pieces; sternum large, forming in front a moveable door or lid which can hermetically close the aperture of the osseous box. The posterior part of the sternum furnished right and left with a cartilaginous operculum, shutting the apertures which give passage to the hind feet; there is a third operculum besides to stop the opening whence the tail issues.

C. granosus (*Trionyx granosus*, Schweigg.). It lives in fresh-water lakes. The flesh is eaten. *C. Senegalensis.*

Family IV. Thalassians, Sea-Tortoises, or Turtles. (*Cheloniadæ*, Gray; *Carettoids*, Fitzing.; *Halychelones*, Ritgen; *Oiacopod Tortoises*, Wagl.).

This family is at once distinguished from all the others by the comparatively depressed carapace and the long and broad paddles, the anterior of which are very much prolonged when compared with the posterior ones. Indeed their limbs are entirely so modified as to become swimming organs.

The Turtles hardly ever leave the sea excepting for the purpose of laying their eggs; but some accounts state that they will crawl up the shores of desert islands in the night, and clamber up the edges of isolated rocks far at sea, for the purpose of browsing on certain favourite marine plants. They have been seen in smooth water as far as 700 or 800 leagues from the land, floating motionless on the surface of the sea as if they were dead, and it has been supposed that they are then asleep. They dive well, and can remain beneath the surface a long time, as might be expected from the extent and volume of their arbi[illegible] lungs, capable of retaining and furnishing a sufficient quantity of [illegible] while they are submerged.

Messrs. Duméril and Bibron speak of the Potamians and Turtles as exceptions to the rest of the *Chelonia*, which, generally speaking, can produce no other sounds than hisses: we find however from Mr. Darwin's account above given, that the Great Land-Tortoises, the males at least, bellow loudly at the pairing season. The cries of the Potamians and of some Thalassians have been noticed by observers, and especially those of the Coriaceous Turtle, or *Sphargis*. Individuals of this last genus, when hampered in nets or grievously wounded, have been heard to utter loud roars, from which they derive their name (σφαραγίζω, to roar, or cry loudly).

The food of the Thalassians consists principally of marine plants; but it appears that some of them, especially those which exhale a musky odour, *Chelonia Caouana* (*Caouana*, Gray), for instance, feed also on crustaceans and many species of mollusks, the cuttles especially. Their jaws are robust, like the beaks of birds of prey; solidly articulated and worked with highly developed muscles; and their horny beak, hooked above and below, is trenchant on the edges, and most frequently serrated, so as to assist in securing a slippery prey.

Whilst little is known with regard to the conduct of the two sexes during the breeding season, those attending the deposit of the eggs are better known. To reach the destined spot, the females have often to traverse the sea for more than fifty leagues, and the males accompany them to the sandy beaches of those desert islands selected for the places of nidification. Arrived at the end of their voyage, they timidly come forth from the sea after sunset; and as it is necessary to leave the eggs above high-water mark, they have often to drag themselves to a considerable distance before they can hollow out their nests (about two feet in diameter) during the night, and there lay at one sitting to the number of a hundred eggs. This laying is repeated thrice, at intervals of two or three weeks. The eggs vary in size, but are spherical, like tennis-balls; and when they are laid, their investing membrane is slightly flexible, although covered with a delicate calcareous layer. After slightly covering the nest with light sand, the parent returns to the sea, leaving the eggs to the fostering influence of a tropical sun. The eggs are said to be hatched from the 15th to the 29th day; and when the young turtles come out, their shells are not yet formed, and they are white as if blanched. They instinctively make for the sea; but on their road, and as they pause before entering the water, the birds of prey that have been watching for the moment of their appearance hasten to devour them; whilst those that have escaped their terrestrial persecutors by getting into the sea, have to encounter a host of voracious fishes and legions of ambushed crocodiles.

Those that escape attain, under favourable circumstances, enormous dimensions. Individuals of the genus *Sphargis* have been known to weigh from 1500 lbs. to 1600 lbs.; and some whose carapace has measured in its circumference more than 15 feet, and near 7 feet in length, have weighed down more than from 1800 lbs. to 1900 lbs. Aged turtles often carry about with them on their carapace a little world of parasites, such as *Flustræ*, *Serpulæ*, *Balani*, and *Coronulæ*; whilst certain *Annelides* securely fix themselves at the origin or base of the limbs, where the motion of the turtle cannot displace them.

Though many of the other *Chelonia* are highly useful to man, especially as articles of food, none are of such great utility as the Thalassians. The advantages to be derived from them were not lost upon the ancients; and though Mercury is said to have taken the first hint for the structure of a lyre from the dried carapace and tendons of a tortoise (a *Gymnopus*, probably), found by the god after an inundation of the Nile, and which sounded when he struck 'the chorded shell,' the benefits arising from the Thalassians are, if not so refined, of a much more substantial and varied nature. The inhabitants of those countries where the turtles grow to a large size do not merely derive from them a supply of food, but they convert their carapaces into boats, into huts, into drinking-troughs for their domestic animals, and baths for their children. The *Chelonophagi* of old, who inhabited the shores of India and the Red Sea, converted the enormous shells of the turtles which they caught into roofs for their houses and boats for their little voyages, as Strabo and Pliny testify. The latter, in the tenth chapter of his ninth book, enters at large upon the subject.

As an article of food the Green Turtles (Tortues Franches of the French), are so highly prized, that they have become a considerable article of commerce. The fat of many species, when fresh, is used with success in lieu of butter and oil in cookery; and in those species which have a musky odour (*Chelonia Caouana* and *C. Caretta* for instance), is used for embrocations, leather-dressing, and as lamp-oil.

The Imbricated Turtles furnish that valuable article tortoise-shell, or rather the best sorts of it, so highly prized in ancient and modern times, and so ornamental and useful in the arts. The eggs of all the species, particularly those of the Green Turtles, are excellent.

In proportion to the benefits derived from the spoils of the turtles, the ingenuity of man has been sharpened by his eagerness to acquire them. One of the most obvious methods of capture was, and is, to watch the females as they emerge from the sea to deposit their eggs, and then turn them upon their backs on the high and dry sand, where they helplessly remain till the captors come to fetch them on the morrow. When the turtles lie floating on the sea, either for the purposes of sleep or respiration, the turtle-fishers approach them quietly with a sharp harpoon, carrying a ring at the butt-end, to which a cord is attached. The harpooner strikes, and the wounded animal dives, but is at last secured by the cord. In the South Seas skilful divers watch them when so floating, and, getting under the animals, suddenly rise, and so seize them. Mr. Darwin, with his usual felicity, describes another method of capture. In his account of Keeling Island, he says :—"I accompanied (April 6, 1836) Captain Fitzroy to an island at the head of the lagoon: the channel was exceedingly intricate, winding through fields of delicately branched corals. We saw several turtles, and two boats were then employed in catching them. The method is rather curious: the water is so clear and shallow, that although at first a turtle quickly dives out of sight, yet in a canoe or boat under sail, the pursuers, after no very long chase, come up to it. A man standing ready in the bows at this moment dashes through the water upon the turtle's back; then clinging with both hands by the shell of the neck he is carried away till the animal becomes exhausted, and is secured. It was quite an interesting chase to see the two boats thus doubling about, and the men dashing into the water, trying to seize their prey." ('Journal.')

But the most extraordinary mode of fishing is that said to be practised towards the coasts of China and the Mozambique, where turtles are taken by the aid of living fishes trained for the purpose, and thence named Fisher-Fishes. The fact appears to have been known to Columbus, and has been verified by Commerson and cited by Middleton and Salt. The fish is a species of *Echeneis* or *Remora*, and the islanders who use it are said to proceed in the following manner:—They have in their little boat tubs containing many of these fishes. The upper part of the head of the fish is covered with an oval plate, soft and fleshy at its circumference. In the middle of this plate is a very complicated apparatus of bony pieces, disposed across in two regular rows, like the laths of Persian blinds. The number of these plates varies from 15 to 36, according to the species; they can be moved on their axis by means of particular muscles; and their free edges are furnished with small hooks, which are all raised at once like the points of a wool-card. The tail of each of the trained fishes in the tubs is furnished with a ring for the attachment of a fine but long and strong cord. When the fishermen perceive the basking turtles on the surface of the sea, knowing that the slightest noise would disturb the intended victim, they slip overboard one of their Remoras tied to the long cord, and pay out line according to their distance from the turtles. As soon as the fish perceives the floating reptile he makes towards it, and fixes himself to it so firmly that the fishermen pull in both fish and turtle to their boat, where the fish is very easily detached by pushing its head in a direction from behind forwards, and the turtle is secured.

Chelonia, Brongn. (*Caretta*, Merrem).—Body covered with horny scales or shells. One or two nails on each foot.

Sub-Genus 1.—Chelonées Franches. Green Turtles.

Discoidal plates to the number of thirteen, not imbricated. Muzzle short, rounded. Upper jaw with a slight notch in front and small dentilations on the sides; horny case of the lower jaw formed of three pieces and having its sides deeply dentilated. A nail on the first toe of each foot.

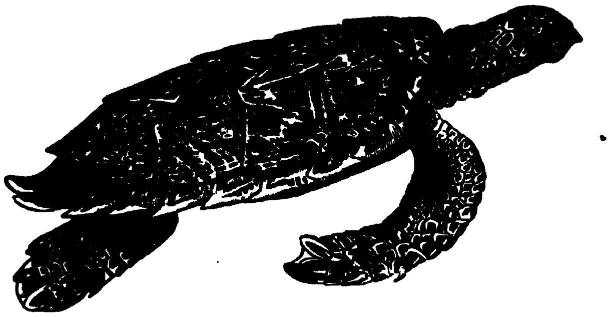
C. Mydas. Messrs. Duméril and Bibron observe that this and the three following species are so similar, that it is possible for them to form one species only: but they add that this question can only be satisfactorily solved by those who have opportunities of comparing the living animals.

C. virgata; C. maculosa; C. marmorata.

Sub-Genus 2.—Imbricated Chelones.

Plates of the disc imbricated and thirteen in number. Muzzle long and compressed. Jaws with straight edges without dentilations, curved slightly towards each other at their extremities. Two nails on each fin.

C. imbricata, the Hawk's-Bill Turtle of Catesby and Brown (*Caretta imbricata*, Gray; *Testudo imbricata* Linnæus). Flesh bad. Eggs very good.



Hawk's-Bill Turtle (*Chelone imbricata*).

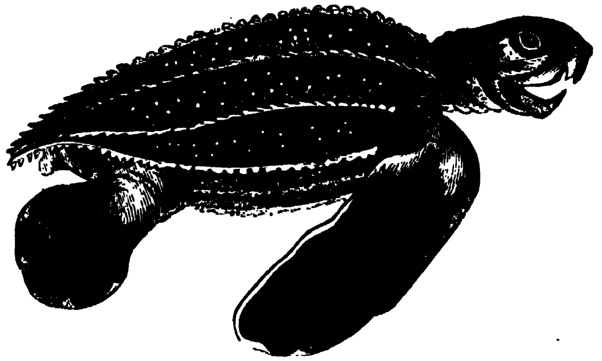
Sub-Genus 3.—Chelonées Caouanes. Logger-Head Turtles.

Plates of the carapace not imbricated. Fifteen plates on the disc. Jaws slightly curved towards each other at their extremity.

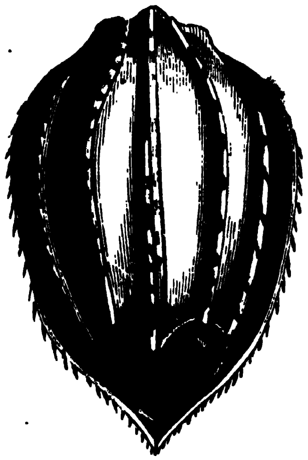
C. Caouana, the Logger-Head Turtle of Catesby (*Caouana Caretta*, Gray); *C. Dussumierii* (*Chelonia olivacea* of Eschscholtz; *Caouana olivacea*, Gray).

Sphargis, Merrem (*Coriudo*, Flem.; *Dermatochelys*, Blainv.).—Body enveloped in a coriaceous hide, tuberculous in young subjects, completely smooth in adults. Feet without nails.

S. coriacea (*Testudo Lyra*, Donnd. and Bechst.; Tortue Luth of the French; Coriaceous Tortoise of Pennant).



Sphargis coriacea.



Plastron of *Sphargis coriacea.*

This turtle has been taken on many of the European coasts; several of large size (700 lbs. and 800 lbs. in weight) have been captured on those of Britain. One case, where the capture was effected off the coast of Scarborough, should be a warning not to use it rashly as food. Pennant relates that one of the three taken in 1748 or 1749 was purchased by a family, who invited several persons to partake of it. A gentleman present told the guests that the flesh was unwholesome, but one of the company persisted in eating of it, and suffered most severely, being seized with dreadful vomiting and purging; and yet the Carthusians, Pennant tells us, are said to eat no other species. It would seem, then, that the severe effect above noticed must have been accidental, and the animal may have been in an unhealthy condition. It is said to grow very fat; but the flesh is reported to be coarse and bad. The French name is given probably upon the supposition that it was the species used by the ancients in the early construction of the lyre.

This and the last-named turtle are the only species of the *Chelonia* that have been taken alive on the British coasts. Professor Bell in his 'British Reptiles' expresses his conviction that several of the "fresh-water species, both of Europe and North America, might be naturalised in the southern parts of England. The *Terrapene Europæa*," he says, "the common Lacustrine Tortoise of the continent, is found in Portugal, Spain, Italy, and Greece, in France, and even in Prussia. These tortoises are eaten by the inhabitants of all the countries in which they are found; and as they live principally upon small fish, the air-bags of which they reject; it is said that the people are wont to judge of the quality of the tortoises to be found in a lake or pond by the number of air-bags which are seen swimming on the surface of the water. I once placed in a small pond, in which were some of these Fresh-Water Tortoises, six small living fish, and on the following morning I found the air-bags of five of them floating on the surface of the water and the sixth fish still alive. In some parts they are fed upon grains and other nourishing food, and fattened for the table. There are also several American species of *Emys*, or Fresh-Water Tortoise, which will bear a greater degree of cold than that of most of our winters without perishing; and it is certainly desirable that a wholesome and agreeable food, like that afforded by some of these, should not be lost to us, if the species can be easily perpetuated and multiplied in our climate."

Several species of Fresh-Water Tortoises are now in the collection of the Zoological Society, in the Aquavivarium of the Regent's Park Gardens.

The following list of *Chelonia*, arranged according to their geographical distribution, is from Dr. J. E. Gray's, 'Catalogue of the Tortoises and Crocodiles, &c., in the Collection of the British Museum.' When a species is found in two of the larger divisions of the list on account of its extensive range, it is preceded by an asterisk.

Europe.

Fossil Chelonia.

Cuvier, in his treatise upon Fossil Tortoises, observes that the number of living species is so considerable that it is very difficult to decide whether a fossil tortoise is or is not of an unknown species; inasmuch as it is not only necessary, before arriving at this conclusion, to compare the carapaces and plastrons covered with their horny plates or scales, as they are ordinarily seen in cabinets and represented in books, but also the skeletons, so that the observer may accurately study the joining of the ribs and other bones which concur to compose their cuirasses. He names twenty-nine species that he himself had stripped of their covering, and says that he had performed that operation on others beside.

Cuvier commences his description with the fossil *Trionyces*, and distinguishes—1, those from the gypsum-beds of the environs of Paris; 2, those from the gypsum-beds of Aix; 3, those from the 'molasse' of the department of the Gironde; 4, those from the gravel and clay-beds of Hautevigne in the department of the Lot and Garonne; 5, those from the gravel-beds in the neighbourhood of Castelnaudry; and 6, those from the sandy beds in the environs of Avaray.

He next considers the *Emydes*, or Fresh-Water Tortoises, noticing—1, those from the Paris gypsum-beds; 2, those discovered together with crocodiles in the Jurassic limestone of the neighbourhood of Soleure; 3, those of the ferruginous sand of Sussex; 4, those of the 'molasse' of La Grave and those of the 'molasses' of Switzerland; 5, those from our Isle of Sheppey; 6, those from the environs of Brussels; and 7, those from the marly sand (sable marneux) of the province of Asti.

The Marine Tortoises, or true Chelonians, he divides into—1, those of the environs of Maestricht; and 2, those of the slate of Glaris.

The Land-Tortoises noticed are—1, those of the environs of Aix; and 2, those found in the Isle of France under the volcanic beds.

The conclusions drawn by Cuvier are, that the Tortoises are as ancient inhabitants of the world as the Crocodiles; that they accompany the remains of the latter generally; and that as the greater number of their remains belong to fresh-water or terrestrial species they confirm the conjectures drawn from the bones of crocodiles as to the existence of isles or continents which were frequented by reptiles before the existence of viviparous quadrupeds, or at least before there was a sufficient number of these last to afford a quantity of remains at all comparable to those of reptiles.

Professor Owen, in his elaborate 'Report on British Fossil Reptiles,'—drawn up at the request of the British Association for the Advancement of Science, and published in their Transactions—gives the following account of the order *Chelonia*:—

I. Family *Testudinidæ*, Tortoises, or Land-Tortoises.

1. New Red-Sandstone Tortoises. The most ancient of the evidences of Chelonians in British formations appear to Professor

Owen to be referrible to the Land-Tortoises; and he quotes the footprints from the quarries at Corncockle Muir, and those subsequently discovered at the quarries of Craigs, two miles east of Dumfries, as examples. [AMPHIBIA.]

2. Oolite Tortoises. Examples. Impressions of horny scutes about the size of those covering the carapace of a tortoise, ten inches in length, in the Oolite Slate of Stonesfield.

II. Family *Emydidæ*, Fresh-Water Tortoises.

1. An undetermined species in the museum of Professor Bell, from the Eocene Clay near Harwich.

2. *Emys testudiniformis*, Owen (Emys de Sheppey, Cuv.?). Sheppey.

3. *Platemys Bowerbankii*, Owen. Sheppey.

4. *Platemys Bullockii*, Owen. Sheppey.

5. *Tetrosternon punctatum*, Owen. Purbeck Limestone. N.B. Closely allied to *Trionyx*.

6. With regard to *Platemys Mantelli* (Emys de Sussex, Cuv., *Emys Mantelli*, Gray), Professor Owen remarks that the fossils discovered by Dr. Mantell in the Wealden strata of Tilgate Forest, and the resemblance of which to the flat species of Emydian discovered by M. Hugi in the Jura Limestone at Soleure has been pointed out by Cuvier, are referrible to the plurođeral section of the Emydian family as arranged by Messrs. Duméril and Bibron, and in that section to the genus *Platemys* (*Hydraspis*, Bell); but that not enough of the skeleton of any individual has yet been obtained to afford a foundation for specific character.

7. Large Emydian from the Kimmeridge Clay. A bone in the museum of Sir P. Grey Egerton, Bart., from Heddington Pits, probably belonging to a species of *Platemys*.

8. Footsteps of Emydians in New Red-Sandstone. Stourton Quarries, Cheshire.

With regard to the genus *Trionyx*, Professor Owen remarks that certain British fossils from the Secondary Formation referred to *Trionyx* have been proved to belong to another family of Chelonians: the supposed *Trionyx* from the New Red-Sandstones (Caithness) has been pronounced to be a ganoid fish (genus *Coccosteus*) by Agassiz. Nor had Professor Owen when he wrote (1841) seen any Chelonite from the Wealden Formation that could be confidently affirmed to belong to *Trionyx*.

A femur from the Lias at Linksfield in the possession of Mr. Robertson of Elgin, 4½ inches in length, and found with remains of *Plesiosaurus* and *Hybodus*, though not identical in form with any *Trionyx* with which Professor Owen could compare it, he found to resemble the modifications of the bone in that genus more closely than in Tortoises, Emydians, or Turtles. He remarks that although some of the Turtles of the Eocene period, as the *Chelone longiceps*, present such modifications of the jaws as seem to have adapted them to habits and food analogous to those of the *Trionyx*, yet evidences of this genus, to which the destruction of the eggs and young of crocodiles is more particularly assigned in the Nile and Ganges, are not wanting in certain localities where the London Clay appears to have been deposited under circumstances analogous to those at the termination of equally gigantic rivers; and he adds that unequivocal portions of a true *Trionyx* have been obtained from the Eocene Clay at Sheppey and at Bracklesham, and that they are also associated, as in the Paris basin, with remains of *Anoplotherium* and *Palæotherium* in the Eocene Limestone deposits in the Isle of Wight.

III. Family *Chelonidæ*, Thalassian Family, or Turtles.

1. *Chelone planiceps*, Owen. Portland Sandstone.

2. *C. obovata*, Owen. Purbeck Limestone.

3. An undetermined species of *Chelone* from the Wealden. Portions of the carapace, plastron, and bones of the extremities of a large species of Marine Turtle, some of them indicating individuals nearly three feet in length, discovered by Dr. Mantell in the Wealden strata of Tilgate Forest, are figured in the Doctor's 'Illustrations of the Geology of Sussex.' This species, in Professor Owen's opinion, comes nearest to *C. planimentum* of the Harwich Eocene Clay.

4. *C. pulchriceps*, Owen. Superincumbent beds of the Lower Greensand; Greensand near Barnwell, Cambridge.

5. *C. Benstedi*, Owen (*Emys Benstedi*, Mantell). Chalk; Burham, Kent.

In a monograph on the 'Fossil Reptilia of the London Clay,' by Professors Owen and Bell, published by the Palæontographical Society, the following species are described, and figures of the remains found, given.

Order—*Cheloniæ*.

Family—*Marina*.

Genus—*Chelone*.

1. *C. breviceps* (*Emys Parkinsonii*, J. E. Gray; Emys de Sheppey, H. V. Meyer; *Chelone antiqua*, König). Eocene Clay of Sheppey.
2. *C. longiceps*. Eocene Clay of Sheppey.
3. *C. crassicostata*. Harwich Clay.
4. *C. declivis*. Eocene Deposits of Bognor, Sussex.
5. *C. trigoniceps*. Eocene Clay at Bracklesham.
6. *C. cuniceps*. London Clay of Sheppey.
7. *C. subcarinata*. Sheppey.

Remarking on the descriptions of these species, Professor Owen says, "A retrospect of the facts above detailed relative to the Fossil Chelonians of the genus *Chelone*, or marine family of the order, leads to conclusions of much greater interest than the previous opinions respecting the Chelonites of the London Clay could have suggested. Whilst these fossils were supposed to have belonged to a fresh-water genus, the difference between the present fauna and that of the Eocene period, in reference to the Chelonian order, was not very great; since the Emys, or *Cistuda Europæa*, still abounds on the Continent, after which it was named, and lives long in our own island in suitable localities.

"But the case assumes a very different aspect when we come to the conviction that the majority of the Eocene Chelonites belong to the true marine genus *Chelone*; and that the number of species of these extinct Turtles already obtained from so limited a space as the Isle of Sheppey, exceeds that of the species of *Chelone* now known to exist throughout the globe. Notwithstanding the assiduous search of naturalists, and the attraction to the commercial voyager which the shell and the flesh of the Turtles offer, all the tropical seas of the world have hitherto yielded no more than five well-defined species of *Chelone*; and of these only two, as the *C. Mydas* and *C. Caouana*, are known to frequent the same locality. It is obvious, therefore, that the ancient ocean of the Eocene epoch was much less sparingly inhabited by Turtles; and that these presented a greater variety of specific modifications than are known in the seas of the warmer latitudes of the present day.

"The indications which the English Eocene Turtles, in conjunction with other organic remains from the same formation, afford of the warmer climate of the latitude in which they lived, as compared with that which prevails there in the present day, accord with those which all the organic remains of the oldest Tertiary deposits have hitherto yielded in reference to this interesting point.

"That abundance of food must have been produced under such influences cannot of course be doubted; and we may infer that to some of the extinct species, which like the *Chelone longiceps* and *C. planimentum* exhibit either a form of head well adapted for penetrating the soil, or with modifications that indicate an affinity to the *Trionyces*, was assigned the task of checking the undue increase of the now extinct crocodiles and gavials of the same epoch and locality, by devouring their eggs, or their young becoming probably in return themselves an occasional prey to the older individuals of the same carnivorous Saurians."

Family—*Fluvialia*.

Genus—*Trionyx*.

1. *T. Henrici*. Eocene at Hordwell.
2. *T. Barbaræ*. Eocene at Hordwell.
3. *T. incrassatus*. Eocene Formations of the Isle of Wight.
4. *T. marginatus*. Eocene Deposit at Hordwell Cliff.
5. *T. rivosus*. Eocene Beds at Hordwell Cliff.
6. *T. planus*. Eocene at Hordwell and Bracklesham.
7. *T. circumsulcatus*. Eocene at Hordwell.
8. *T. pustulatus*. Clay at Sheppey.

Family—*Paludinosa*.

Genus—*Platemys*.

1. *P. Bullockii*. London Clay.
2. *P. Bowerbankii*. Clay at Sheppey.

Genus—*Emys*.

1. *E. testudiniformis* (Emys de Sheppey, Cuvier?). Eocene Clay of Sheppey.
2. *E. lævis*. Clay of Sheppey.
3. *E. Comptoni*.
4. *E. bicarinata*.
5. *E. Delabechii*. London Clay, Isle of Sheppey.

Amongst the Fossil remains brought from the Tertiary Formations of India by Dr. Falconer and Major Cautley, are those of a gigantic species of Land-Tortoise. The species referred to has been named *Colossochelys Atlas*. Portions of its skeleton and a model of the entire animal are now in the collection of the British Museum. The carapace of this gigantic animal measures in some specimens above 12 feet in length. These remains were found associated with the bones of gigantic extinct *Mammalia* allied to *Palæotherium*, and the other *Pachydermata* of the Paris basin. In the same deposits were also found the remains of several smaller species of *Chelonia*, and of the one which now inhabits India. There have been also found in the same locality the remains of gigantic crocodiles, differing from those now inhabiting India, and several species of elephant.

In the 'Reports' of the United States Surveying Expedition in Wisconsin, Iowa, and Minesota, in 1850, an account is given of the discovery of the remains of a large number of species of *Chelonia*, both Tortoises and Turtles, with the remains of extinct forms of *Mammalia* in the district of the Mauvaises Terres on the Missouri.

CHELO'NIA (Godart), a genus of Lepidopterous Insects, of the section *Nocturna* (Latreille), and family *Arctiidæ* (Leach). Before we proceed with an account of this genus, which contains two of the most conspicuous and beautiful of the British moths, it may be well briefly to state the characters of the family *Arctiidæ*, as far as the diversified habit of the species will admit. The palpi are two in number, mostly 3-jointed and hairy. The antennæ have a double series of pectinations; thorax large; the apex of the body generally furnished with a tuft; wings closing so as to form an angle by their junction, or folding horizontally. The males are usually larger than the females; larvæ generally very hairy, frequently furnished with numerous tufts, those on the tail and towards the head the longer.

The genus *Chelonia* is synonymous with *Arctia* of Schrank. The latter name is generally adopted by British entomologists from its priority. The term *Chelonia* is open to another objection, being commonly used to designate a section of Tortoises.

Arctia Caja, the Large Tiger-Moth, or the Garden-Tiger, is very common in the south of England, but apparently less so in the north. The expanded wings measure from 2¼ to 3 inches in width; the upper wings are of a chocolate-brown colour, with numerous irregular cream-coloured markings; the under wings are scarlet, with five or six large blue-black spots; the body is also scarlet, or pinkish above, with several transverse black bands; on the under side the ground-colour is black, with pink bands; the head and thorax are brown, separated with a red ring; the legs are red at the base, and the antennæ are white.

The caterpillar of this moth is found in great abundance near London, and is frequently seen crawling on pathways: it is covered with long black hairs, and when touched will roll itself up in a ring: it feeds upon a great variety of plants, but seems most fond of lettuce, groundsel, and chickweed. The larva is found in the spring months, and turns into a pupa about June. The pupa is inclosed in a loose web of a white colour; the moth appears in the autumn.

This species is extremely variable in its imago state; we have seen specimens in which the upper wing is nearly all white, and others in which the white is almost obliterated: the spots on the under wing vary also considerably; they sometimes run one into the other so as to form a band.

Arctia Villica, the Cream-Spot Tiger-Moth, is the only other well authenticated British species; it is far less abundant than the other. The upper wings are black, with about eight large cream-coloured spots; the under wings are yellowish, spotted more or less with black, and has an irregular black fascia near the margin; the abdomen is reddish, spotted with black; the head and thorax are black; the latter has two cream-coloured spots.

The caterpillar very much resembles the one last described, but has a red head, and legs of the same colour; like the last it feeds upon various plants, particularly the chickweed. The moth appears about the end of June, and is rather less than the Large Tiger.

CHELONIANS. [Chelonia.]

CHELYS. [Chelonia.]

CHEMNITZIA, a genus of Shell-Fish belonging to the Prosobranchiate section of the *Gasteropoda*, and referred to the family *Pyramidellidæ*. [Pyramidellidæ.]

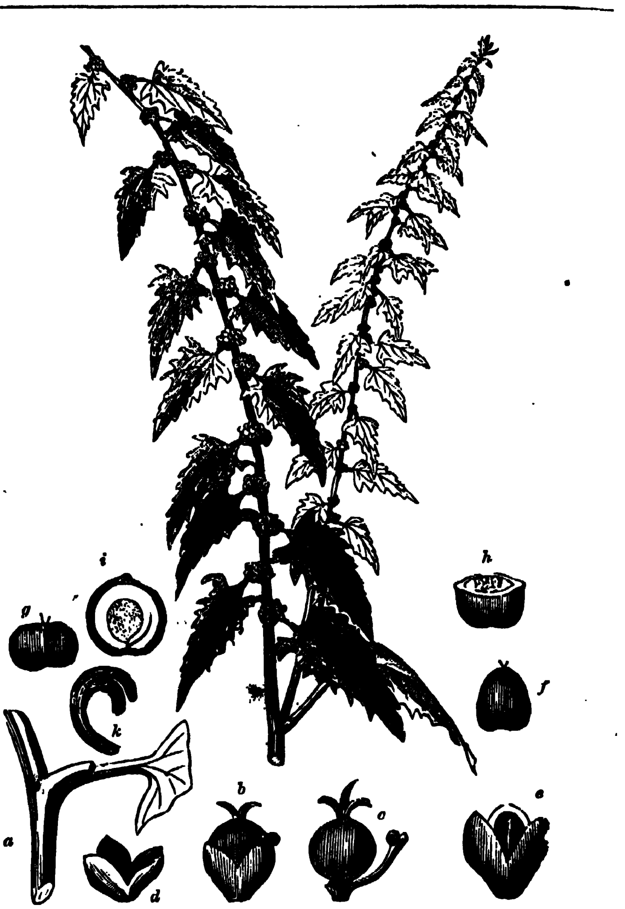
CHENALOPEX, a genus of Birds belonging to the family *Anatidæ*, to which the Egyptian Goose (*C. Ægyptiaca*) is referred. [Ducks.]

CHE'NNIUM, a genus of Coleopterous Insects. [Pselaphus.]

CHENOCOPROLITE, a Mineral of a yellow or pale-green colour, belonging to the silver series, and supposed to be an arseniate of silver and iron.

CHENOPODIA'CEÆ, *Chenopods*, the Chenopodium Tribe, a natural order of Exogens, consisting of numerous species, used either for culinary purposes or for the manufacture of soda. They are apetalous plants, with minute green herbaceous flowers, a small number of stamens, which are opposite the segments of the calyx, and a one-celled membranous fruit, containing one single erect seed, or a very small number. The leaves are soft and rather succulent, without any trace of stipules. Most of them are found in the cold and temperate parts of the world. They differ from *Polygonaceæ* and *Urticaceæ* in the want of stipules, and from *Amarantaceæ* in their flowers not being coloured and enveloped in membranous bracts. This order embraces plants of opposite characters, and when better investigated will probably be split up. Schleiden has observed that certain species have the wood very compact, and pierced with vertical cords of cellular tissue. The order contains 63 genera and 360 species. They are natives of all parts of the world, in waste and uncultivated places. Spinach [Spinacia], Fat Hen, Good King Henry [Chenopodium], Garden Orach [Atriplex], Chard-Beet, Beet, Mangold Wurzel [Beta], belong to this order. Soda is obtained from species of *Salsola* and *Salicornia*. [Salsola; Salicornia.]

CHENOPO'DIUM, a genus of plants the type of the natural order *Chenopodiaceæ*. It consists of weedy plants, common on dunghills and in waste places, and known by the strange names of Fat Hen (*C. album*), Good King Henry (*C. Bonus-Henricus*), &c. They are generally insipid plants, whose leaves and young shoots may be eaten as spinach, but which have no particular merit. In this genus is however found the celebrated Quinoa of Peru (*C. Quinoa*). This plant, whose seeds are said to be of as much importance to the Peruvians as the maize, potato, and wheat, is an annual weedy species, with an appearance similar to that of Garden Orach, to the size of which it grows. Its flowers appear in close clusters about the ends of the branches, and are succeeded by a profusion of little black or white seeds (according to the variety) about the size of grains of millet. Its leaves are employed as spinach, and the seeds in soup or broth as rice, and in some parts of South America they are in as much use as rice in India. They are said to yield a pleasant beer when fermented. It is chiefly upon the highest land of Southern Peru, where neither barley nor rye will ripen, as, for instance, at the height of nearly 13,000 feet on the table-land of Chiquitos, that Quinoa forms the great article of agriculture; it there forms fields, the limits of which the eye can hardly reach, of a monotonous and unpleasant aspect, scarcely mixed with a single other species, and very unlike the rich and waving greenness of our standing corn. It is also extremely common about the great lake of Titicaca. The seeds are ripened in England, and may now be purchased at any of the seed-shops; but the plant can hardly be considered worth the attempt at cultivating it where anything else will grow. *C. olidum* has an atrocious odour, and has a reputation as an antispasmodic and emmenagogue.



Chenopodiaceæ. Blitum virgatum.

a, angle of the petiole, showing the peduncle; *b*, flower; *c*, flower deprived of its calyx, showing the ovary, surmounted by three pistils; *d*, calyx; *e*, fruit imbedded in the succulent calyx; *f*, *g*, fruit separated from the calyx; *h*, horizontal section of fruit; *i*, vertical do.; *k*, embryo. All these figures, excepting *a*, magnified in various degrees.

The following is an analysis of the British species of *Chenopodium*.

* Perianth enveloping the fruit.
  † Leaves undivided.
    Leaves ovate rhomboidal. *C. olidum.*
    Leaves ovate-elliptical. *C. polyspermum.*

  †† Leaves toothed, angled, or lobed.
    Leaves triangular. *C. urbicum.*
    Leaves sinuate-dentate. *C. album.*
    Leaves unequally 3-lobed. *C. ficifolium.*
    Leaves rhomboid-ovate. *C. murale.*
    Leaves subcordate. *C. hybridum.*

** Perianth not covering the fruit.
  † Stigmas short.
    Leaves rhomboid. *C. rubrum.*
    Leaves triangular. *C. botryoides.*
    Leaves oblong. *C. glaucum.*

  †† Stigmas elongated.
    Leaves triangular. *C. Bonus-Henricus.*

CHERIMOYER, the fruit of a Peruvian downy-leaved species of *Anona*, the *A. Cherimolia*. It is described as the fruit most esteemed by the people of the western parts of South America, and is very like the Custard Apple of the West Indies. [Anona.] It is a tree about 12 feet high; the leaves are oval, pointed at both ends; the flowers solitary, very fragrant, of a greenish-white colour, and the fruit somewhat heart-shaped, with a scaly appearance on the outside: when ripe it is grayish-brown, or black. The flesh is white and sweet, mixed with several seeds of the colour of coffee. The Creoles think this fruit the best of the country. Baron Humboldt speaks of it in terms of high praise, and his account is completely confirmed by the testimony of many officers who have been in the South American service; but Feuillée says, one European pear or plum is worth all the Cherimoyers of Peru.

CHERLE'RIA, a genus of plants belonging to the natural order *Caryophyllaceæ.* It has 5 sepals, 5 petals (sometimes absent), 10 stamens, the outer ones opposite to the sepals, springing from an oblong emarginate glandular base, 3 styles, a 3-valved capsule. There is only one species which is a native of Great Britain. It was called by Linnæus *C. sedoides.* The petals are very generally wanting, the flowers are solitary on short stalks. The stems are numerous, forming a dense mass close to the ground. The leaves are very numerous, linear-subulate, and finely ciliated. It is found on the summits of the mountains of Scotland.

CHERRY, the fruit of the various species of *Cerasus.* [Cerasus.] Like most of the fruits yielded by the natural order *Amygdalaceæ,* it is characterised by the hardness of its endocarp, hence this part is often called the stone. This hard part is often used for ornamental carving, specimens of which may be seen in the museum of the Royal Gardens at Kew. For the varieties of Cherry, and the culture of the tree, see Cherry, in Arts and Sc. Div.

CHERRY-LAURELS. [Cerasus.]

CHERRY-TREES. [Cerasus.]

CHERSIANS. [Chelonia.]

CHERT, a variety of quartz being a kind of granular Chalcedony. It is a transition from the smoother forms of Quartz to Hornstone. [Agate.]

CHERVIL, a culinary vegetable, the *Anthriscus Cerefolium* [Anthriscus] of botanists. It is an annual, and a native of the south of Europe. Its leaves have a slight aromatic taste, and are used in soups and salads. It is little cultivated.

CHESTNUT, BUCK'S-EYE. [Pavia.]

CHESTNUT, HORSE. [Æsculus.]

CHESTNUT, SWEET. [Castanea.]

CHIASTOLITE is a name given to a variety of *Andalusite.* [Andalusite.] It is also called *Macle.* [Macle.]

CHICA. [Bignonia.]

CHICHA. [Sterculia.]

CHICK-PEA. [Cicer.]

CHICKRASSIA, a genus of plants belonging to the natural order *Cedrelaceæ.* *C. tabularis* is said to be a powerful astringent.

CHICKWEED, a common annual, with soft light-green opposite ovate leaves, a brittle stem, and minute white petals, almost split into two parts. It and groundsel are two plants which are to be found in flower on any day in the year. Botanists name it *Stellaria media.* [Stellaria.]

CHICORY. [Cichorium.]

CHIFF-CHAFF. [Sylvia.]

CHIGOE. [Pulex.]

CHILDRENITE, a Mineral found in Derbyshire. It occurs in minute yellowish-brown crystals, coating spathic iron. It is supposed to consist of phosphoric acid, alumina, and iron.

CHILINA, a genus of Testaceous Mollusks, separated by Dr. J. E. Gray from *Auricula,* and including *Auricula Dombeiana* of Lamarck, and *Auricula fluviatilis* of Lesson. Locality, South America, in fresh-water streams, with most of the habits of the *Limneæ.*

CHILLIES. [Capsicum.]

CHILLINGHAM CATTLE. [Bovidæ.]

CHILO'GNATHA (Latreille), an order of Insects belonging to the class *Myriapoda.* It has the following characters:—Body generally cylindrical, and consisting of numerous crustaceous rings or segments; the head is furnished with two short 7-jointed antennæ, and two mandibles; the horny substance of the mandibles does not continue uninterruptedly from the base to the apex, but is divided in the middle so that the upper part is, as it were, hinged to the lower by a tough membrane; they are covered above by the fore part of the head, which forms a kind of upper lip, and beneath by an under lip; this last part is divided externally into four portions by three sutures; the two central portions are narrower than the outer ones, and spring from a plate of a semicircular shape; the apex of the under lip is furnished with several large tubercles. The first segment of the body, or that next the head, is considerably larger than the following segments. The legs are short, very numerous, and terminated by a simple hook; the anterior segments of the body are some of them unprovided with legs, and others have a single pair each; the remaining segments (with the exception of the last two or three) commencing from the fourth, fifth, or sixth from the head, are each furnished with two pairs of legs. The sexual organs of the male are situated behind the seventh pair of legs, and those of the female behind the second pair. The respiratory orifices are situated on the sternal part of each segment of the body; they communicate internally with a double series of pneumatic sacs which extend the whole length of the body, and from which the tracheal branches spring and spread over the other organs; these sacs are not connected with each other, as is usually the case, by a principal trachea. A series of pores on each side of the body have been mistaken for the stigmata, but their orifices give vent to an acid liquid secretion which has a very disagreeable odour, and probably serves as a means of defence.

The *Chilognathæ* crawl slowly, and appear to glide over the ground, and when touched they will roll themselves up spirally. They feed upon decaying animal and vegetable substances. The genus *Iulus* of Linnæus [Iulus] included all the species of this order known in his time. It now embraces several genera and upwards of seventy species. [Myriapoda.]

CHILO'PODA (Latreille), an order of Insects belonging to the class *Myriapoda.* This family is synonymous with the order *Syngnatha* (Leach), and the genus *Scolopendra* of Linnæus. The characters are:—Antennæ thick at the base, and gradually growing slender towards the apex, composed of fourteen or more joints; the mouth consists of two mandibles, which are furnished with a palpiform process, and provided at the apex with numerous little denticulations; covering these is an upper lip and an under lip; the latter is composed of four distinct portions, of which the two outer parts are the largest, and transversely jointed; above this part (viewing the head from beneath) are two palpi, which resemble legs in being terminated by a pointed claw: covering this under lip, there is a second lip, an organ furnished with two lateral processes, each of which is terminated by a large bent claw, which is said to be perforated beneath by a hole through which a poisonous liquid is ejected.

The body is depressed, composed of numerous segments, which are covered above and beneath with plates of a horny substance, and each segment is generally furnished with a pair of legs; the last pair are thrown back. The sexual organs are placed at the posterior extremity of the body. The organs of respiration consist wholly or partly of tubular tracheæ. The stigmata are placed on the sides of the body.

These insects are carnivorous, and crawl about by night. Most of them are very active in their movements, and some emit a phosphoric light. They conceal themselves under stones and fallen trees, and are all found in rotten wood. In hot climates some of the species grow to an immense size (especially those of the genus *Scolopendra,* as it is now restricted), and, owing to their venomous bite, are much dreaded by the inhabitants of those parts.

The animals commonly known by the name of Centipedes belong to this family. [Scolopendra.]

The species of this order have been recently greatly increased. It now embraces nearly a hundred species. [Myriapoda.]

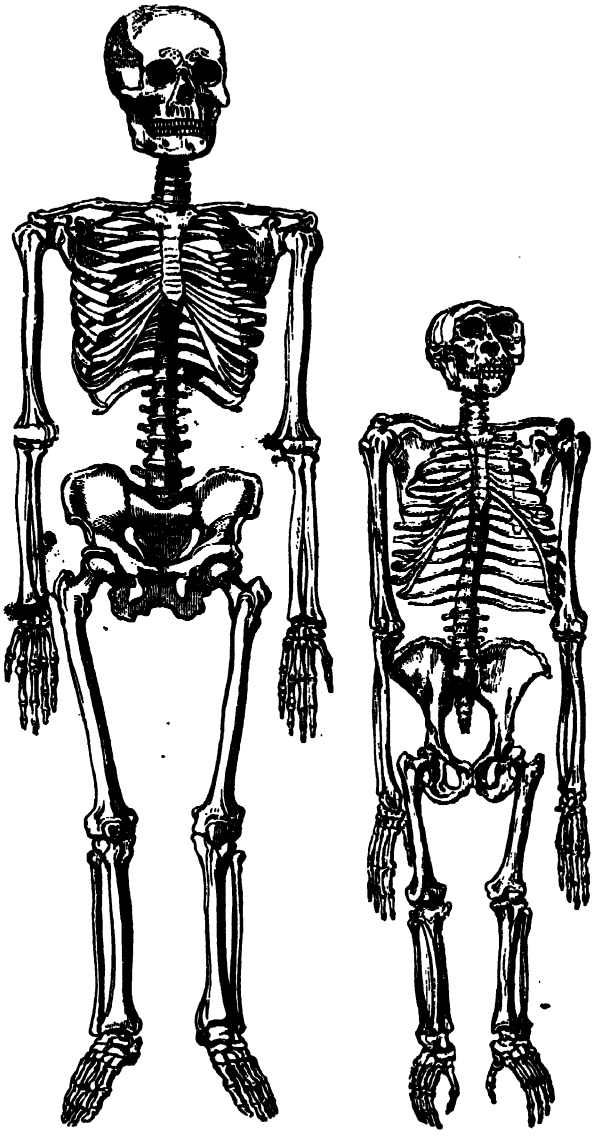
CHIMÆ'RA, a genus of Cartilaginous Fishes allied to the Sturgeon and Shark sections. [Sturionidæ.] One species, *C. monstrosa,* inhabits the British seas, and is known by the names of the King of the Herrings, the Rabbit-Fish, and Sea-Monster.

CHIMÆRIDÆ, a family of Fishes between the Sharks and the Sturgeons, to which is referred the anomalous genus *Chimæra.* [Sturionidæ.]

CHIMA'PHILA, a genus of plants belonging to the natural order *Pyrolaceæ.* *C. corymbosa* (Pursh), the *Pyrola umbellata* of Linnæus, the Corymbose Wintergreen, is a small evergreen woody plant, common in the pine-forests of the north of Europe, also found in Asia and in North America, to the Indian inhabitants of which its virtues have been long known. The leaves possess diuretic properties joined to a tonic power, and they impart strength and comfort to the stomach while they increase the action of the kidneys. Applied externally, they cause redness and vesication of the skin. Chemical analysis shows them to consist of tannin, resin, and an acrid extractive. The taste is at first sweet, afterwards bitter. Their tonic and diuretic properties render them valuable remedial agents in dropsies, especially such as follow acute diseases. They have also been given advantageously in intermittent and even typhus fever. Dr. Chapman ascribes a diaphoretic power to them. Infusion, decoction, and extract are the forms in which they have been given: decoction is preferable, of which some ounces may be given repeatedly during the day.

CHIMONA'NTHUS, a genus of plants belonging to the natural order *Calycanthaceæ.* The species or rather varieties of this genus are called in the gardens Japan Allspice. They are deciduous plants, with opposite pale-green sharp-pointed rather rough leaves, of an ovate-lanceolate figure. About the end of November these fall from the bushes, and are succeeded by the flowers, which appear at Christmas-time upon the naked branches. They consist of an inferior calyx, formed of a considerable number of roundish scale-like sepals, the outermost of which are pale brown, the innermost semi-transparent, with some tinge of yellow. The petals are yellowish ovate leaves, stained with chocolate-red veins, and surrounding a small number of stamens. The fruit is a bright-brown leathery calyx-tube, inclosing three or four oblong bright-brown polished nuts. There is probably no plant more deliciously fragrant than this, orange flowers and violets not excepted. The plant is quite hardy if protected a little by a wall or by palings. The only species is *C. fragrans.* Of this three varieties are known in the gardens; the common kind, *C. fragrans*, with [illegible] pale-yellow flowers; the *C. f. grandiflorus*, with large bright-yellow flowers; and another, *C. f. parviflorus*, with flowers resembling those of the first, except in being much smaller. The last is not worth cultivating; both the former should be found in every garden, however small. Nothing can be more elegant as room-ornaments than handfuls of their round flowers placed on little porcelain trays.

CHIMPANZEE, the name by which one of those forms which approach nearest to man is most generally known. The term has been applied to the *Simia Satyrus* of Linnæus, the Oriental Orang; but zoologists are now agreed in its proper application to the Black or African Orang or Pygmy (*Troglodytes niger* of Geoffroy, *Simia Troglodytes* of Blumenbach). Linnæus placed the form under the genus *Homo*, with the specific name *Troglodytes*, next to *Homo sapiens*, arranging, as we have seen above, the Asiatic Orang under the *Simiæ*. But he seems to have confounded the two species of Orangs, which differ very considerably; for he refers to the figure given by Bontius, which was intended for the Asiatic, and yet he gives, quoting Pliny, the borders of Ethiopia as its habitat, as well as Java, Amboyna, Ternate, and Mount Ophir in Malacca. That the Chimpanzee, though much of its organisation bears a striking resemblance to that of Man, is separated from him by a wide interval, the accurate investigations of modern anatomists sufficiently prove. Tyson, Camper, Blumenbach, Cuvier, Lawrence, and especially Owen, have set that question at rest, though Bory de St. Vincent struggled hard to retain Man and the Orangs as members of the same zoological family. Before we refer to the arguments of the last-named zoologist and his followers, it will be necessary to apprize the reader that, to say nothing of the difference of organisation in other parts of the body and foot, the heel-bone (os calcis) of man does not project backwards so far in proportion as that of the Chimpanzee, and Lawrence notes this as an infallible human characteristic; '*ex calce* hominem.' Bory de St. Vincent, and those who support the theory of gradual development of animal form, endeavour to show that the position of the great toe, upon which its conversion into an opposeable organ, or thumb, and the consequent transmutation of the foot into a hand, principally depends, is a character subject to modification; and, after a somewhat sweeping assumption that it is the only difference of organisation between the Orangs and Man, points the whole strength of his argument against its value as a zoological character; and, by a rather retrograde process of reasoning, endeavours to support his views by giving an instance where man, under certain circumstances, obtains a prehensile power of foot. Calling in aid the Resiniers of the Landes of Aquitaine, he exhibits them as having acquired a power of opposing the great toe to the others, a faculty supposed to have been arrived at by their scansorial habits in obtaining their living by gathering the resin of *Pinus maritima*. "But," as Professor Owen well observes, "supposing the extent of motion of the great toe to be sufficiently increased by constant habits of climbing, or in connection with a congenital defect of the upper extremities, yet it does not appear that the os calcis, or the other bones of the foot, have lost any of those proportions which so unerringly distinguish man from the ape." M. Bory, however, in his zealous endeavours to lower the arrogance which makes man unwilling to fraternise with apes and monkeys, is carried so far as to give vent to this naïve question :—"En effet, quatre mains ne vaudraient elles pas mieux que deux comme élémens de perfectibilité?"—"In fact, are not four hands of more value than two as elements of perfectibility?" Now, let us look at this fallacy, for a fallacy it is. There might be a little, and a very little after all, in the query, if any one of the four hands of the *Quadrumana*, or all of them put together, approached the hand of man as an instrument of action,—an instrument whereby, though born the most helpless of animals and without clothing or any natural protection, he has made himself master of all, and compelled the apparently most impracticable natural productions to minister not only to his wants but to his most luxurious imaginations. Let any one who is at all conversant with animal mechanics look at the hand of a Chimpanzee, and compare it with his own; or let any one observe the Chimpanzee using his apology for a thumb, and then cast his eyes on the merest hodman at his work, and he will soon see where the advantage lies. And this is not all. "To give due force to this proposition," says Professor Owen in his paper 'On the Osteology of the Chimpanzee and Orang-Utan,' "the four hands of the ape ought to be independent of any share in stationary support or progression. Now, it is scarcely necessary to observe that the perfection of the hands of man results, in a great measure, from the free use he is enabled to make of them in consequence of the organisation of the lower members as exclusive instruments for sustaining and moving the body. It has, however, been suggested that the hallux (thumb) of the orang might acquire increased length and strength during the efforts of successive generations to maintain the erect position; but if we look a little further into the anatomy of the orangs, a difficulty presents itself unforeseen by Lamarck and Bory. The muscle called 'flexor longus pollicis pedis' terminates, in the human subject, in a single tendon, and its force is concentrated on the great toe, the principal point of resistance in raising the body upon the heel. In the orang, however, the analogous muscle terminates in three tendons, which are inserted separately and exclusively in the three middle toes, obviously to enable these to grasp with greater force the boughs of trees, &c. It is surely asking too much to require us to believe that in the course of time, under any circumstances, these three tendons should become consolidated into one, and that one become implanted into a toe, to which none of the three separate tendons were before attached. The myology of the orangs, to which I may hereafter endeavour to direct more attention than it has yet received, affords many arguments equally unanswerable against the possibility of their transmutation into a higher race of beings." From the same author we take the following summary comparison of the Chimpanzee and Orang-Outan with each other, and with man :—



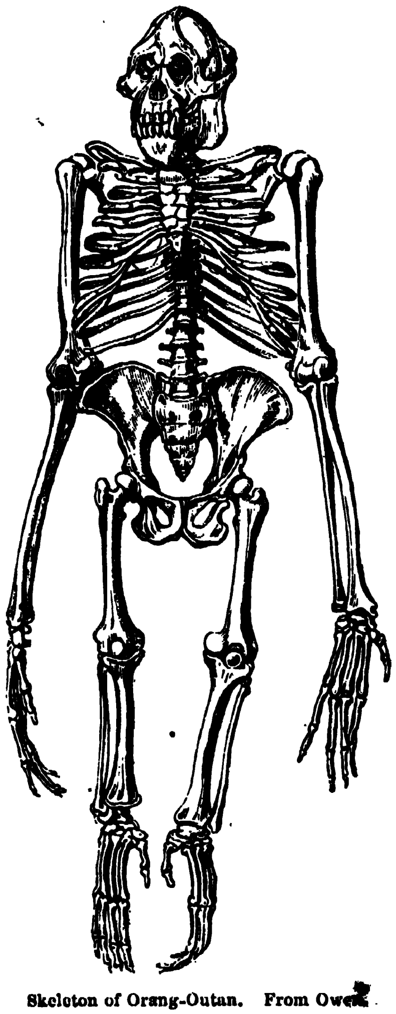
Skeleton of Man. Skeleton of Chimpanzee. From Owen.

The Chimpanzee differs osteologically from the Orang :—1. In having the cranium flatter and broader in proportion to the face. 2. In having the supraciliary ridges more developed, and in the absence of the interparietal and sagittal crests. 3. In the junction of the temporal with the frontal bones. 4. In the greater proportional breadth of the interorbital space. 5. In the more central position and less oblique plane of the occipital foramen. 6. In having but one anterior condyloid foramen on each side, while the orang has two. 7. In having generally but one suborbital foramen on each side, while the orang has three or more. 8. In the persistence of the cranial sutures. 9. In the earlier obliteration of the maxillo-intermaxillary sutures. 10. In the smaller proportional size of the incisive and canine teeth, and consequent smaller development of the jaws, especially of the intermaxillary bones. 11. In the smaller proportional size of [illegible] cervical vertebræ, and larger proportional size of the lumbar vertebræ. 12. In the additional dorsal vertebra corresponding to the additional pair of ribs. 13. In the more complete composition of the sternum, which consists of a single and not double series of bones, as in the orang. 14. In the greater sigmoid curve of the clavicle, which in the orang is nearly straight. 15. In the less proportional breadth of the scapula, and the more lateral aspect of the glenoid cavity. 16. In the less proportional breadth and greater length of the [illegible] 17. In the less proportional breadth of the ilium, and greater expansion of the ischium. 18. In the comparative shortness of the upper extremities, more especially of the fore-arm and hand. 19. In the non-division of the pisiform bone of the wrist. 20. In the greater proportional length of the femur and tibia, and the less proportional length of the foot. 21. In the presence of a ligamentum teres, and consequent depression in the head of the femur. 22. In the greater proportional size of the tarsus as compared with the phalanges of the toes. 23. In having constantly two phalanges in the hallux or great toe with a nail, while the ungueal phalanx and nail are often wanting in the hallux of the orang, especially in that of the female.

The chimpanzee approximates more nearly to the human structure in those deviations which are numbered 4, 5, 6, 7, 8, 9, 10, 12, 13, 17, 18, 19, 20, 21, 22, 23.

The orang has a nearer resemblance to man :—1. In the junction of the sphenoid with the parietal bones. 2. In having twelve pairs of ribs. 3. In the form of the scapula, especially in its greater breadth.

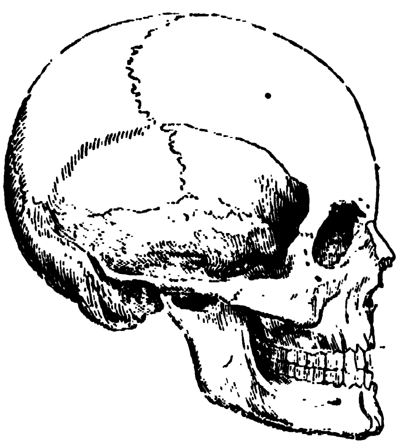
Owen well observes that it is a result of the preceding comparison that the chimpanzee ought to rank above the orang in a descending series, and not below it as in the 'Règne Animal' of Cuvier. Linnæus, as we have seen, gave the chimpanzee that superiority of rank, but erred as much on the other side by placing it under the genus *Homo*, for both the chimpanzee and orang, according to Owen, differ in structure from the human subject :—1. In the diastema, or interval between the cuspidati and incisors in the upper jaw, and between the cuspidati and bicuspides of the lower jaw. 2. In the greater magnitude of the intermaxillary bones, indicated in the adult by the distance of the foramina incisiva from the incisive teeth ; both of which differences result from the greater proportional development and different forms of the cuspidati and incisors. These, as the author observes, are differences of generic value. 3. In the more backward position and oblique plane of the occipital foramen. 4. In the smaller proportional size of the occipital condyles. 5. In the larger proportional size of the petrous bones. 6. In the greater proportional development of the jaws. 7. In the flatness of the nasal bone, which is rarely divided in the mesial line, while in man the nasal bones are as rarely consolidated into one. 8. In the presence of the ant-auditory process of the temporal bone, and the absence of the mastoid and styloid processes. 9. In the absence of the process of the ethmoid, called crista galli. 10. In the shortness and comparative weakness of the lumbar region of the spinal column; which is also composed of four instead of five vertebræ. 11. In the narrowness and proportional length of the sacrum. 12. In the flatness of the ilia, and the larger development and outward curvature of the ischia. 13. In the position of the pelvis in relation to the spine. 14. In the larger proportional development of the chest. 15. In the greater length of the upper extremities. 16. In the wider interval between the ulna and radius. 17. In the shortness and weakness of the thumb, and narrowness of the hand in relation to its length. 18. In the shortness of the lower extremities. 19. In the greater proportional length and narrowness of the foot. 20. In the small size of the os calcis. 21. In the shortness and opposeable condition of the hallux.



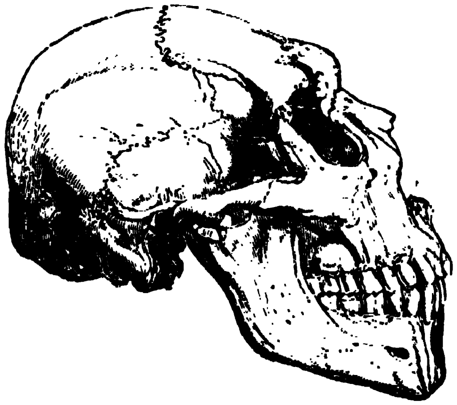
Skeleton of Orang-Outan. From Owen.

"These differences," adds Professor Owen, "result from original formation, and are not liable to be weakened in any material degree, either on the one hand, by a degradation of the human species, or, on the other hand, by the highest cultivation of which the anthropoid apes are susceptible."

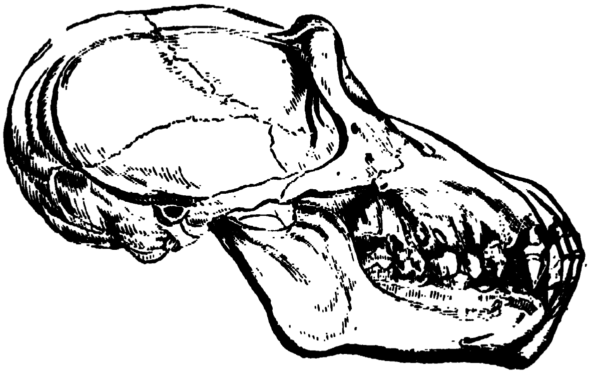
In following out this osteological comparison it becomes necessary, for the assistance of the student, to give a sketch of the cranial



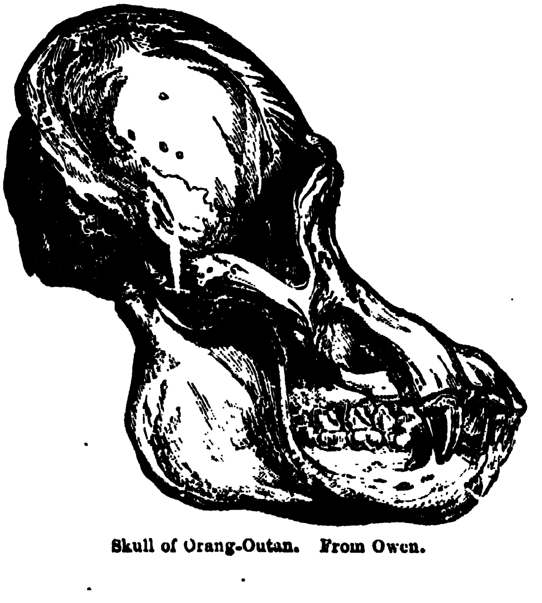
Well-developed Human Skull.



Skull of Human Idiot. From Owen.



Skull of Chimpanzee. From Owen.



Skull of Orang-Outan. From Owen.

development in man and in the anthropoid apes, so that he may have under his eye the comparative form of each.

We cannot do better than give the following conclusive statements of Professor Owen.

"Certain modifications in the form of the human pelvis have been observed to accompany the different forms of the cranium which characterise the different races of mankind; but there is nothing in the form of the pelvis of the Australian or Negro which tends to diminish the wide hiatus that separates the bimanous from the quadrumanous type of structure in regard to this part of the skeleton. Observation has not yet shown that the pelvis of the orang, in a state of captivity, undergoes any change approximating it towards the peculiar form which the same part presents in the human subject. The idea that the iliac bones would become expanded and curved forwards, from the pressure of the superincumbent viscera, consequent on habitual attempts at progression on the lower extremities, is merely speculative. Those features of the cranium of the orangs which stamp the character of the irrational brute most strongly upon their frame, are however of a kind, and the result of a law, originally impressed upon the species, which cannot be supposed to be modified under any circumstances, or during any lapse of time; for what external influence operating upon and around the animal can possibly modify in its offspring the forms, or alter the size, of the deeply-seated germs of the permanent teeth? They exist before the animal is born; and let him improve his thinking faculties as he may, they must, in obedience to an irresistible law, pass through the phases of their development, and induce those remarkable changes in the maxillary portion of the skull which give to the adult orangs a more bestial form and expression of head than many of the inferior *Simiæ* present. It is true that in the human subject the cranium varies in its relative proportions to the face in different tribes, according to the degree of civilisation and cerebral development which they attain; and that in the more debased Ethiopian varieties, and Papuans, the skull makes some approximation to the quadrumanous proportions: but in these cases, as well as when the cranium is distorted by artificial means or by congenital malformation, it is always accompanied by a form of the jaws, and by a disposition and proportions of the teeth, which afford unfailing and impassable generic distinctions between man and the ape. To place this proposition in the most unexceptionable light, I have selected the cranium of a human idiot, in whom nature may be said to have performed for us the experiment of arresting the development of the brain almost exactly at the size which it attains in the chimpanzee, and where the intellectual faculties were scarcely more developed; yet no anatomist would hesitate in at once referring this cranium to the human species. A detailed comparison with the cranium of the chimpanzee or orang shows that all those characters are retained in the idiot's skull which constitute the differential features of the human structure. The cranial cavity extends downwards below the level of the glenoid articulatory surfaces. The nasal bones are two in number, and prominent. The jaws and teeth exhibit the bimanous characters as strongly as in the most elevated of the human race. The cuspidati do not project beyond the contiguous teeth, and consequently there are no interruptions in the dental series, as in the orangs, where they are required to lodge the disproportionate crowns of the canine teeth."

M. Geoffroy St. Hilaire characterised the sub-genus *Troglodytes* from immature Chimpanzees; and as Professor Owen's observations were made upon the skeleton of an adult individual, and he has consequently altered the zoological characters given by Geoffroy, we follow Professor Owen's definition.

Sub-Genus *Troglodytes.*

Dental formula the same as in the human subject; namely, incisors, $\frac{4}{4}$; canines, $\frac{2}{2}$; bicuspids, $\frac{4}{4}$; molars, $\frac{6}{6} = 32$.

The teeth approximate in their proportionate size much more nearly than those of the orang to the human teeth; but they manifest in their relative position the absence of the character which, with one anomalous exception—that of the fossil genus *Anoplotherium*—is peculiar, among mammifers, to man; namely, unbroken proximity. Muzzle long, truncated anteriorly; strong supraciliary ridges, behind which the forehead recedes directly backwards; no cranial ridges. Facial angle 35°, excluding the supraciliary ridges. Auricles large. Thirteen pairs of ribs; bones of the sternum in a single row. Arms reaching below the knee-joint. Feet wide; hallux extending to the second joint of the adjoining toe. Canines large, overpassing each other; the apices lodged in intervals of the opposite teeth. Intermaxillary bones anchylosed to the maxillaries during the first or deciduous dentition.

Troglodytes niger (Geoffroy), *Simia Troglodytes* (Blumenbach), the Chimpanzee, Black Orang, or Pigmy. In the young state the animal has been named Jocko.

The following is the description by Dr. Traill of a young female, about 30 inches high, which was brought to Liverpool by Captain Payne:—"The skin appears of a yellowish-white colour, and is thinly covered with long black hair on the front; but it is considerably more hairy behind. The hair on the head is rather thin, and is thickest on the forehead, where it divides about an inch above the orbital process of the frontal bone, and running a little backwards falls down before the ears, forming whiskers on the cheeks. Here the hair measures nearly two inches long; but that on the occiput is not above an inch in length. There are a few stiff black hairs on the eyebrows, and a scanty eyelash. A few whitish hairs are scattered on the lips, especially on the under one. The rest of the face is naked, and has whitish and wrinkled skin. There is scarcely any hair on the neck; but, commencing at the nape, it becomes somewhat bushy on the back. The abdomen is nearly naked. The hair on the back of the head, and the whole trunk, front of the lower extremities, back of the legs, and upper part of the superior extremities is directed downwards, while that on the back of the thigh and fore-arms is pointed upwards—appearances well represented in Tyson's figure. The longest hair is just at the elbows. There is none on the fingers or palms of either extremity. The ears are remarkably prominent, thin, and naked, bearing a considerable resemblance in shape to the human, though broader at the top. The projection of the process above the eyes is very conspicuous, but has not been sufficiently marked in any engraving or drawing which has fallen under my observation. The nose is quite flat, or rather appears only as a wrinkle of the skin with a slight depression along its centre. The nostrils are patulous and open upwards, which would be inconvenient did the animal usually assume the erect posture. The projection of the jaws is excessive, and though much less so than in the baboon, yet the profile of the face is concave. It may be remarked however that the projection of the lower jaw is caricatured in the first and second figures of Camper's second plate. The mouth is wide, the lips rather thin and destitute of that recurvation of the edges which adds so much to the expression of the human countenance. The spread of the shoulders is distinctly marked, but the width of the lower part of the chest is proportionally greater when compared to the upper than in man. From the lower ribs the diameter of the abdomen decreases rapidly to the loins, where the animal is peculiarly slender—a circumstance in which it approaches the other *Simiæ*. The pelvis appears long and narrow, another approximation to the rest of the genus. With regard to the limbs, the chief difference between our specimen and Dr. Tyson's figure consists in the excessive length of the arms, which in this animal descend below the knees, by the whole length of the phalanges of the fingers, which are above three inches in length. The same observation applies to almost every figure of this animal which I have seen. The proportions in the work of Camper approach nearest, in the present instance, in this particular. The hand differs from the human in having the thumb by far the smallest of the fingers. The foot is more properly a hand appended to a tarsus. The thumb of this extremity is very long, powerful, and capable of great extension. The legs are certainly furnished with calves; but they scarcely resemble the human in form, because they are continued of equal thickness nearly to the heel. When this animal is erect the knees appear considerably bent, as is the case with the other *Simiæ*, and it stands with the limbs more apart than man." This description applies to the various specimens of this creature which have been exhibited in the Gardens of the Zoological Society in Regent's Park, London. At the present time (November 1853) a young male is in the collection. The last specimens were a male and female; the latter died of consumption, and her disconsolate companion soon followed.

Africa is the only part of the world known to be the residence of the Chimpanzee, which it should be remembered has been confirmed, as Cuvier observes, by almost all zoologists. The specimen described by Dr. Traill was procured in the Isle of Princes, in the Gulf of Guinea, from a native trader, who had carried it thither from the banks of the Gaboon. The individual exhibited in the Egyptian Hall, Piccadilly, in 1831, had been obtained by a trading vessel on the river Gambia; and those exhibited at the Gardens of the Zoological Society have all been brought from the coast of Africa. Cuvier gives Guinea and Congo as its localities. The subject of Professor Owen's paper was shot by a European at Sierra Leone.

Habits.—The habits of the Chimpanzee in a state of nature are but imperfectly known. Cuvier states that the Chimpanzees live in troops, construct themselves huts of leaves, arm themselves with sticks and stones, and employ these weapons to drive man and the elephant from their dwellings. He also repeats the story of their pursuit of the negresses and carrying them off into the woods. This report is still credited in the country where they are found. Speaking of Captain Payne, Dr. Traill, in his interesting paper in the 'Wernerian Transactions,' says, "The natives of Gaboon informed him that this species attains the height of five or six feet; that it is a formidable antagonist to the elephant; and that several of them will not scruple to attack the lion and other beasts of prey with clubs and stones. It is dangerous for solitary individuals to travel through the woods haunted by the orang, and instances were related to Captain Payne of negro girls being carried off by this animal, who have sometimes escaped to human society after having been for years detained by their ravishers in a frightful captivity. These reports confirm the narratives of the early voyagers, who have often been suspected of exaggeration; and similar facts have been recently stated, very circumstantially, by gentlemen who have lived in Western Africa." As it is now however well made out that there are two species of Chimpanzee inhabiting the Gaboon, and the larger of the two has not been seen alive in Europe, it is probable the habits of the two animals have been confounded.

In a state of captivity its manners have been the theme of many a tale and much admiration; and as most of the individuals described have died very young, conjecture has been busy as to the progress the animal might make if its education were continued to the adult state. "Deductions," says Professor Owen in his paper above referred to, "in favour of the anthropomorphous character of the orangs have been derived from observation of the living habits of young orangs; but these cannot be regarded as affording a type of the nature of the adults, since it is well known that the docility and gentle manners of the young ape rapidly give way to an unteachable obstinacy and untameable ferocity in the adult; at least of those species to which, as I shall afterwards show, the full-grown orangs have the nearest resemblance in the form of the head."

Chimpanzee (*Troglodytes niger*).

Captain Payne thus describes the manners of the animal which formed the subject of Dr. Traill's paper. "When our animal came on board," says Captain Payne, "it shook hands with some of the sailors, but refused its hand with marks of anger to others without any apparent cause. It speedily however became familiar with the crew, except one boy, to whom it never was reconciled. When the seamen's mess was brought on deck it was a constant attendant would go round and embrace each person while it uttered loud yells, and then seat itself among them to share the repast." It sometimes expressed its anger by a barking noise like a dog; at others it would cry like a froward child, and scratch itself most vehemently. When any favourite morsel was given to it, sweetmeats more especially, it expressed its satisfaction by a sound like 'hem,' in a grave tone. The variety of its tones seems to have been small. It was active and cheerful in warm latitudes, but languor came on as it left the torrid zone; and on approaching our shores it manifested a desire for warm covering, and would roll itself carefully up in a blanket when it went to rest. It generally progressed on all fours, and Captain Payne particularly observed that it never placed the palms of the hands of its anterior extremities on the ground, but closing its fists rested on the knuckles. This mode of progression noticed by Tyson was confirmed to Dr. Traill by a young naval officer who had been for a considerable time employed in the rivers of Western Africa, and had opportunities of observing the habits of this species. Captain Payne's animal did not seem fond of the erect posture, which it rarely affected, though it could run nimbly on two feet for a short distance. In this case it appeared to aid the motion of its legs by grasping the thighs with its hands. It had great strength in the four fingers of its superior extremity; for it would often swing by them on a rope upwards of an hour without intermission. When first procured it was so thickly covered with hair that the skin of the trunk and limbs was scarcely visible until the long black hair was blown aside. It ate readily every sort of vegetable food; but at first did not appear to relish flesh, though it seemed to have pleasure in sucking the leg-bone of a fowl. At that time it did not relish wine, but afterwards seemed to like it, though it never could endure ardent spirits. It once stole a bottle of wine, which it uncorked with its teeth and began to drink. It showed a predilection for coffee, and was immoderately fond of sweet articles of food. It learned to feed itself with a spoon, to drink out of a glass, and showed a general disposition to imitate the actions of men. It was attracted by bright metals, seemed to take a pride in clothing, and often put a cocked hat on its head. It was dirty in its habits, and never was known to wash itself. It was afraid of fire-arms; and on the whole appeared a timid animal. It lived with Captain Payne seventeen weeks, two of which were spent in Cork and Liverpool. At the former place it was exhibited for the benefit of the soup-kitchen for a few days, but seems to have been there neglected. On coming to Liverpool it languished for a few days, moaned heavily, was oppressed in its breathing, and died with convulsive motions of the limbs.

T. Gorilla, Savage (*T. Savagei*, Owen), the Gorilla, or Great Chimpanzee. In the 'Proceedings of the Zoological Society' for 1848 a description is given by Professor Owen of the skulls of adult and aged male and female Chimpanzees from the Gaboon River, much exceeding in size, and specifically distinct from the previously known *T. niger*. At that time Professor Owen proposed to call the species *T. Savagei*, in honour of Dr. Savage, an American missionary, who had first obtained specimens of this Chimpanzee, and described its character and habits. In a letter to Professor Owen, dated "Protestant Mission House, Gaboon River, West Africa, April, 1847," Dr. Savage, after describing the existence of this Chimpanzee, says, "As yet I have been unable to obtain more than a part of a skeleton. It belongs to the *Simiadæ*, and is closely allied to the orangs proper. It reaches nearly, if not quite, the height of five feet in the adult state, and is of a large size. I am considerably in doubt in regard to its identity with an animal said to have been known to Buffon as a large species of orang-outan under the name of Pongo." After the receipt of Dr. Savage's letter and specimens, Professor Owen received skulls from Mr. Stutchbury, of Bristol, which had been collected by Captain Wagstaff, who shortly after died. "The only information which Mr. Stutchbury was able to obtain from him was, that the natives, when they succeed in killing one of these chimpanzees make a 'fetish' of the cranium. The specimens bore indications of the sacred marks in broad red stripes, crossed by a white stripe, of some pigment which could be washed off. Their superstitious reverence of these hideous remains of their formidable and dreaded enemy adds to the difficulty of obtaining specimens."

The following are the points by which the *T. Gorilla* is distinguished from *T. niger*:—

"1. By its greater size. 2. By the size and form of the superciliary ridges. 3. By the existence of the large occipital and interparietal crests in the males, and by rudiments of the same in females. 4. By the great strength and arched form of the zygomatic arches. 5. By the form of the anterior and posterior nasal orifices. 6. By the structure of the infra-orbital canal. 7. By the existence of an emargination on the posterior part of the hard palate. 8. The incisive alveoli do not project beyond the line of the rest of the face, as in the chimpanzee and orang. 9. The distance between the nasal orifice and the edge of the incisive alveoli is less than in the chimpanzee. 10. The ossa nasi are more narrow and compressed superiorly."

Professor Owen concludes his paper on the anatomy of this creature by the following remarks:—"The analogy which the establishment of the second and more formidable species of chimpanzee in Africa has brought to light between the representation of the genus *Troglodytes* in that continent and that of the genus *Pithecus* in the great islands of the Indian Archipelago, is very close and interesting. As the *T. Gorilla* parallels the *Pithecus Wurmbii* [PITHECUS], so the *T. niger* parallels the *P. morio;* and an unexpected illustration has thus been gained of the soundness of the interpretation of the specific distinction of that smaller and more anthropoid orang. It is not without interest to observe that as the generic forms of the *Quadrumana* approach the Bimanous order, they are represented by fewer species. The Gibbons (*Hylobates*) scarcely number more than half a dozen species; *Pithecus* has but two species, or at most three; *Troglodytes* is represented by two species.

"The unity of the human species I regard as demonstrated by the constancy of those osteological and dental characters, to which my attention has been more particularly directed in the investigation of the corresponding characters in the higher *Quadrumana*, and the importance of the comparison will justify the minuteness with which they have been detailed.

"Man is the sole species of his genus, the sole representative of his order; he has no nearer physical relations with the brute kind than those which mark the primary (unguiculate) division of the placental sub-class of *Mammalia*." ('Tran. Zool. Soc.' vol. iii.)

CHINA-BARK, a name given to the bark of *Buena hexandra*, a plant belonging to the natural order *Cinchonaceæ*. It is used as a febrifuge, but is less powerful than the barks obtained from the species of *Cinchona*. [CINCHONACEÆ.]

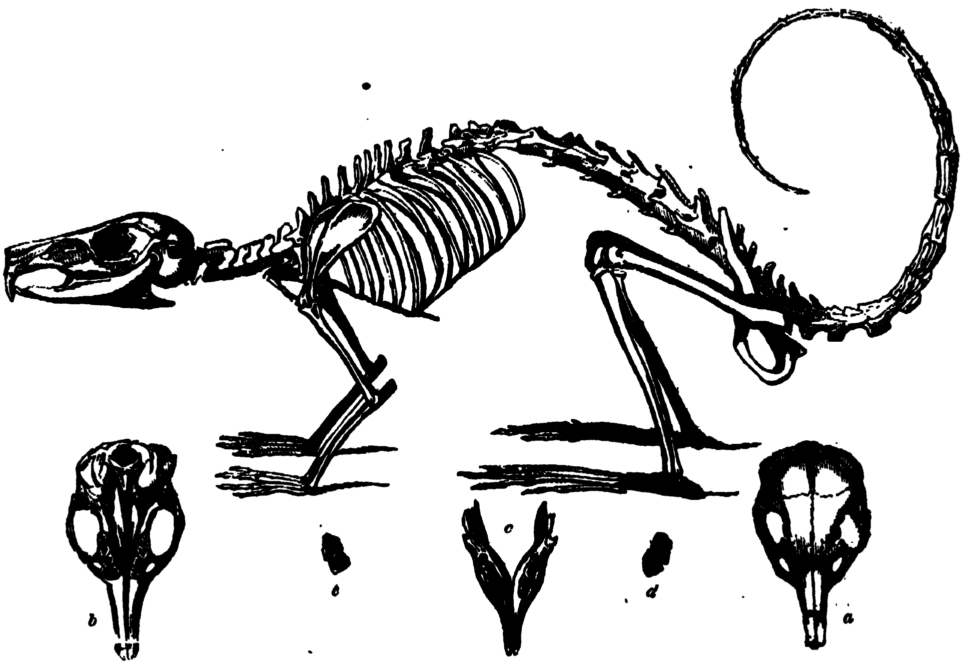
CHINCHI'LLIDÆ, a family of animals belonging to the order *Rodentia*.

This family is defined by Mr. Bennett, to whom we are principally indebted for our knowledge of the species, as follows:—

Upper incisors simple; molars, $\frac{4-4}{4-4}$, consisting of two or three tænial or riband-like bony lamellæ or plates, parallel with each other, entirely surrounded with a vitreous substance; the crowns exactly opposite to each other and flattened by attrition. The posterior limbs nearly twice as long as the anterior. The tail produced, with long and somewhat bristly hairs above and at the tip. The *Chinchillidæ* are gregarious and subterranean in their habits, and mild in disposition. Mr. Waterhouse, in his 'Natural History of Mammalia,' makes the *Chinchillina* a sub-family of the family *Hystricidæ* of the *Rodentia*. It embraces the following genera,—*Lagidium*, *Lagostomus*, and *Chinchilla*.

Lagidium (*Lagotis*, Bennett). Incisors, $\frac{2}{2}$; molars, $\frac{4-4}{4-4} = 20$. The incisors are sharpened, and each molar consists of three complete oblique plates. Skull arched posteriorly and above; the superior cellules of the tympanum inconspicuous. All the feet 4-toed, the great toe being entirely absent; nails long and subfalcular. Ears very long. Tail long. Fur soft, but caducous.

L. Cuvieri, Wagner (*Lagotis Cuvieri*, Bennett). Size and much of the general form of the rabbit. Posterior limbs twice the length of the anterior: tail about equal in length to the body, excluding the head. Whiskers very numerous, closely set, jet black, ten or twelve of the longest on each side being exceedingly thick and rigid, and seven inches long. Ears nearly like a long parallelogram, rounded at the tip, three inches long and one inch broad, with the margins rolled in below, so sparingly furnished with short scattered hairs as to appear almost naked. Fore feet like the hinder, with four toes only, there being no vestige of a thumb; claws small, slightly sharpened, and entirely concealed by long and somewhat bristly hairs; those of the hinder feet similar in shape and rather larger, but that of the inner toe flattened, curved inwards, and exposed, the immediately adjoining hairs giving place to a tuft of about eight rows of short stiff horny curved bristles, approaching nearly in rigidity to the comb-like appendage found in almost the same situation in the *Ctenomys Massonii* of Gray. A similar structure occurs in the *Chinchilla*. The fur is beautifully soft, downy, and of considerable length, but so loosely attached to the skin that it readily falls off, unless handled with care. It is dusky at the base and to within a short distance of the tip, where, for an extent of from one to three lines, it is dirty-white, more or less tinged with yellowish-brown. A few long black hairs, most numerous posteriorly, protrude through it. The general tone of colour is a mottled grayish-ash. On the sides of the neck and body, where the tips of the fur merge more into yellowish-brown than on the back, and where they are also of greater length, as well as on the haunches and beneath, the latter tinge appears rather more predominant. There is little of the dusky colour visible on the under surface. The hairs of the tail below are extremely short, closely depressed, and of a brownish-black; on its sides they are of two kinds, black and white; and this is also the case with the very long rigid and erectile hairs which form a crest along its upper surface. The very long bristly hairs which project in a tuft at the tip are wholly black.



Skeleton of *Lagotis Cuvieri*.

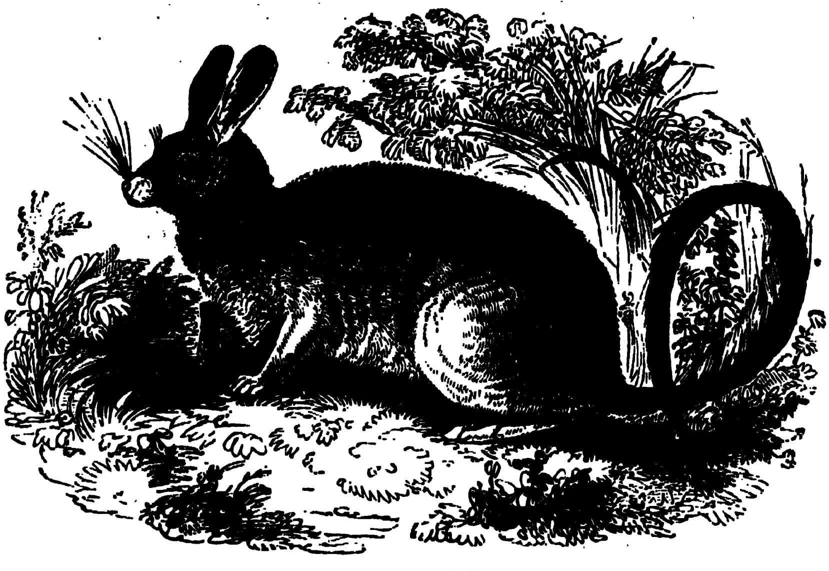
a, Skull seen from above; *b*, the same seen from below; *c*, lower jaw seen from above; *d*, crowns of the two anterior molar teeth of the lower jaw enlarged; *e*, crowns of the two posterior molar teeth of the upper jaw enlarged.

Mr. Bennett believes this species to be the Viscacha of all the writers from Pedro de Cieça downwards, including Acosta, Garcilasso, Peter de Laet, Nieremberg, Feuillée, Ulloa, Vidauré, Molina, Schmidtmeyer, and Stevenson, who have stated that animal to be an inhabitant of the western or Peruvian declivities of the Andes. Messrs. Blainville, Desmarest, and Lesson are among the modern zoologists who have noticed the Viscacha; Lesson, in his 'Manuel,' apparently confounding the eastern and western species, gives it as the *Lepus Viscaccia* of Gmelin, places it among the hares, and quotes Desmarest, as expressing his opinion in his 'Mammalogie,' that it ought to be the type of a new genus under which the *Chinchilla* might be perhaps arranged.

L. pallipes (*Lagotis pallipes*, Bennett). The fur of this species, he observes, is perhaps even softer to the touch than that of *L. Cuvieri*; a feel which is probably owing to its being less dense, on account of the comparative shortness of the hairs composing it; the fur of *L. Cuvieri* imparting to the hand the sensation of fulness and consequent firmness, while that of *L. pallipes* is yielding with its softness. The hairs in both species, especially those which form the mass of the fur, are wavy for the great part of their length, their tips only being straight; those of the middle of the sides measure, when their natural waves are not intefered with, three-quarters of an inch in *L. pallipes*, and an inch and a quarter in *L. Cuvieri*. In neither of these species however is the quality of the fur at all comparable to that of *Chinchilla lanigera*.

The following is the English version (1709) of the passage in Pedro de Cieça's 'Chronica del Peru' (1554), descriptive of the habits of these animals:—"There is another sort of creature they call viscacha, about the bigness of and resembling a hare, but that it has a long tail like a fox. These breed in stony places and among rocks, and many of them are shot with guns and crossbows, and taken by the Indians in gins (with the lasso), they being good to eat after hanging to tender; and of their hair or wool the Indians make large mantles, cloaks, or blankets, as soft as silk, and very valuable." Ulloa's account ('Noticias Americanas,' 1772) is, in the opinion of Mr. Bennett (whose translation we adopt), the best history that has been given of its habits and manners. "Taking the place of the rabbit, which is wanting in Peru, there is another kind of animal called viscacha, which is not found in Quito. In form, and in the colour of its fur, it is similar to the rabbit, but differs from it in having a long tail furnished with tufted hair (like that of the squirrel), which is very thin towards the root, but thick and long as it approaches the tip. It does not carry its tail turned over the head like the squirrel, but stretched out, as it were, in a horizontal direction; its joints are slender and scaly. These animals conceal themselves in holes of the rocks, in which they make their retreats, not forming burrows in the earth like rabbits. There they congregate in considerable numbers, and are mostly seen in a sitting posture, but not eating; they feed on the herbs and shrubs that grow among the rocks, and are very active. Their means of escape do not consist in the velocity of their flight, but in the promptitude with which they run to the shelter of their holes. This they commonly do when wounded; for which reason the mode of killing them is by shooting them in the head; as, if they receive the charge in any other part, although much injured, they do not fail to go and die in the interior of their burrows. They have this peculiarity, that as soon as they die their hair falls off; and on this account, although it is softer and somewhat longer and finer than that of the rabbit, the skin cannot be made use of for common purposes. The flesh is white but not well flavoured, being especially distasteful at certain seasons, when it is altogether repugnant to the palate." Molina speaks of the employment of its wool among the ancient Peruvians, adding that the Chilians of the present day (his work was originally published in 1782, and reprinted with additions in 1810) use it in the manufacture of hats.

Its burrows, according to the report of eye-witnesses, have two flats, communicating by a spiral staircase; in the lower it deposits its food, while it lives in the upper, which it seldom quits except at night. It collects round the mouth of its burrow whatever has been left behind or lost by travellers: and its flesh, which is white and tender, is preferred to that of the rabbit or hare. But this account is liable to the same objections as that in the 'Journal de Physique.' Dr. Tschudi, in his 'Fauna Peruana,' has comfirmed most of these particulars, with regard to the habits of the Viscachas, and also the distinction between the two species above named. *L. Peruanum* of Meyer, and *Callomys aureus* of Geoffroy and D'Orbigny, are probably varieties of *L. Cuvieri*.

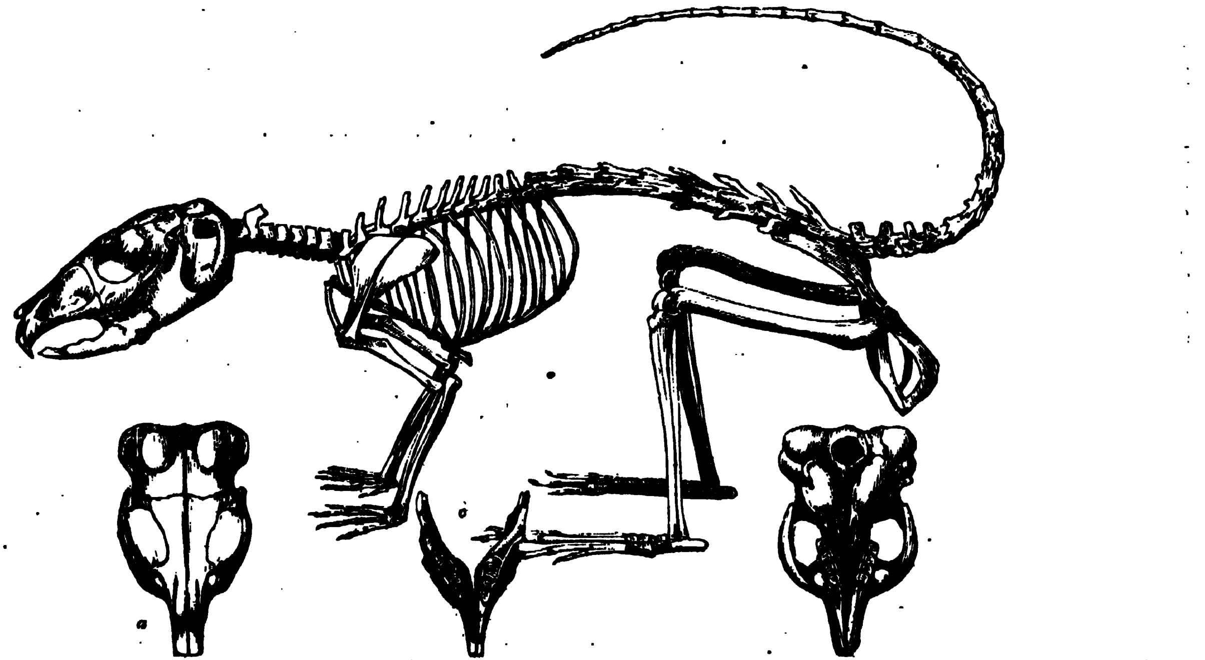


Lagotis Cuvieri.

Chinchilla. Incisors, $\frac{2}{2}$; molars, $\frac{4-4}{4-4} = 20$.

The molars generally consist of three complete oblique plates, except the anterior lower molar, which has but two lamellæ, the anterior lamella being deeply bilobated. Skull posteriorly retuso-truncated, above depressedly flattened; cellules of the tympanum conspicuously inflated. Anterior feet 5-toed, posterior feet 4-toed, the nails small and subfalcular. The ears ample. The tail rather long.

C. lanigera. The length of the body is about nine inches, and that of the tail nearly five. Its proportions are close-set, and its limbs comparatively short, the posterior being considerably longer than the anterior. The fur is long, thick, close, woolly, somewhat crisped, and entangled together, grayish or ash-coloured above, and paler beneath. The form of the head resembles that of the rabbit; the eyes are full, large, and black; and the ears broad, naked, rounded at the tips, and nearly as long as the head. The moustaches are plentiful and very long, the longest being twice the length of the head, some of them black and others white. Four short toes, with a distinct rudiment of a thumb, terminate the anterior foot; and the posterior are furnished with the same number, three of them long, the middle more produced than the two lateral ones, and the fourth, external to the others, very short and placed far behind. On all these toes the claws are short, and nearly hidden by tufts of bristly hairs. The tail is about half the length of the body, of equal thickness throughout, and covered with long bushy hairs; it is usually kept turned upwards towards the back, but not reverted as in the squirrels.



Skeleton of *Chinchilla lanigera.*

a, Skull seen from above; *b*, the same seen from below; *c*, lower jaw seen from above.

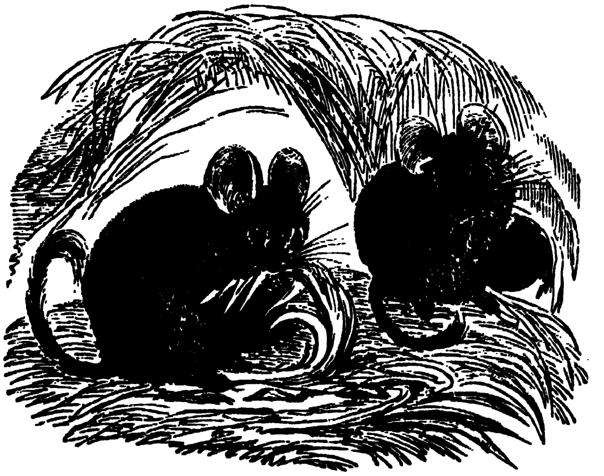
The best account of the anatomy of this animal, from the dissection of one which died in the menagerie of the Society, was given by Mr. Yarrell, in the 'Proceedings of the Zoological Society,' in 1831. In this paper Mr. Yarrell remarks that in some previously published observations, he had stated that the *Chinchilla* appeared to be closely allied to Mr. Brooke's *Lagostomus*, but that the more complicated structure of the teeth, and the existence of an additional toe on each of the feet, require for the *Chinchilla* the generic distinction claimed for it by Mr. Bennett and Dr. J. E. Gray. He adds that the resemblance of the skeleton to that of the *Jerboa* is also remarkable, particularly in the form of the head, in the excessive development of the auditory cavities, and the small size of the anterior extremities compared with the hind legs.

Although an extensive trade has been carried on in the skins of this interesting little animal, it is only within the last few years that it has been seen alive in this country.

The earliest account of this animal, as cited by Mr. Bennett, is an English translation (London, 1604) of Father Joseph Acosta's 'Natural and Moral History of the East and West Indies,' published at Barcelona, in Spanish, in 1591. "The Chinchilles is another kind of small beasts, like squirrels; they have a woonderfull smoothe and soft skinne, which they (the natives) weare as a healthfull thing to comfort the stomacke and those parts that have neede of a moderate heate." Sir John Hawkins, in his 'Voyage into the South Sea, A.D. 1593' (London, small folio, 1622, reprinted in 'Purchas his Pilgrims'), says, "Amongst others they have little beastes, like unto a squirrell, but that he is grey; his skinne is the most delicate, soft, and curious furre that I have seene, and of much estimation (as is reason) in Peru; few of them come into Spaine, because difficult to be come by, for that the princes and nobles laie wait for them; they call this beast Chinchilla, and of them they have great abundance." Alonso de Ovalle, in his 'Historical Relation of the Kingdom of Chili' (Rome, 1646), calls them squirrels. "The squirrels (Ardas) which are found only in the valley of Guasco, are ash-coloured, and their skins are in great esteem for the fineness and softness of the fur." An anonymous Italian author, supposed by some bibliographers—erroneously, as Mr. Bennett thinks—to be the Abbé Vidauré, who published at Bologna, in 1776, a 'Compendium of the Geographical, Natural, and Civil History of the Kingdom of Chili,' speaks of the Arda (Spanish for a squirrel) as a species of rat, or campagnol, of the size of a cat, found only in the province of Copaipo, moderately docile, and covered with ash-coloured wool, as close and delicate as the finest cotton. Buffon, and that too after quoting Feuillée's excellent description, confounded it with the Chinche, the most stinking of beasts. D'Azara corrected this error, but falls into another himself, in regarding the Chinche of Feuillée and Buffon as his Yagouaré. Molina ('Natural History of Chili'—Italian, Bologna, 1782) describes the Chinchilla as a species of Linnæan *Mus*, under the name of *Mus laniger*. Gmelin adopted the appellation, but M. Geoffroy St. Hilaire considered that it ought to be regarded as one of his Hamsters. Zoologists generally took up this opinion, and Molina, in a second edition of his Essay (1810) seems to have entertained it. "The Chinchilla," says Molina, "is another species of field-rat, in great estimation for the extreme fineness of its wool, if a rich fur as delicate as the silken webs of the garden-spiders may be so termed. It is of an ash-gray, and sufficiently long for spinning. The little animal which produces it is six inches long from the nose to the root of the tail, with small pointed ears, a short muzzle, teeth like the house-rat, and a tail of moderate length, clothed with a delicate fur. It lives in burrows underground, in the open country of the northern provinces of Chili, and is very fond of being in company with others of its species. It feeds upon the roots of various bulbous plants which grow abundantly in those parts; and produces twice a year five or six young ones. It is so docile and mild in temper that if taken into the hands it neither bites nor tries to escape, but seems to take a pleasure in being caressed. If placed in the bosom it remains there as still and quiet as if it were in its own nest. This extraordinary placidity may possibly be rather due to its pusillanimity, which renders it extremely timid. As it is in itself peculiarly cleanly, there can be no fear of it soiling the clothes of those who handle it, or of its communicating any bad smell to them, for it is entirely free from that ill odour which characterises the other species of rats. For this reason it might well be kept in the houses with no annoyance, and at a trifling expense, which would be abundantly repaid by the profits on its wool. The ancient Peruvians, who were far more industrious than the modern, made of this wool coverlets for beds and valuable stuffs. There is found in the same northern provinces another little animal with fine wool, called the Hardilla, which is variously described by those who have seen it; but as I have never observed it myself, I cannot determine to what genus it belongs." Upon this, Mr. Bennett, whose translation we have given, remarks that there can be little doubt that this animal is identical with the Chinchilla, the latter being frequently spoken of by the name of Arda, the same with Harda, the diminutive of which is Hardilla. Schmidtmeyer ('Travels into Chile over the Andes,' London, 4to, 1824), thus describes the animal:—"The Chinchilla is a woolly field-mouse, which lives underground, and chiefly feeds on wild onions. Its fine fur is well known in Europe; that which comes from Upper Peru is rougher and larger than the Chinchilla of Chile, but not always so beautiful in its colour. Great numbers of these animals are caught in the neighbourhood of Coquimbo and Copiapo, generally by boys with dogs, and sold to traders who bring them to Santiago and Valparaiso, from whence they are exported. The Peruvian skins are either brought to Buenos Ayres from the eastern parts of the Andes, or sent to Lima. The extensive use of this fur has lately occasioned a very considerable destruction of the animals."

Captain Beechey, R.N., on his return from his expedition to the north-west coast of America, presented a living specimen to the Zoological Society; and an entire skin, rendered particularly valuable in consequence of its having the skull preserved in it, was at the same time brought home by Mr. Collie, the surgeon of Captain Beechey's ship, and deposited in the British Museum.

"To the account of its habits given by Molina," says Mr. Bennett, "we can only add, that it usually sits upon its haunches, and is even able to raise itself up and stand upon its hinder feet. It feeds in a sitting posture, grasping its food and conveying it to its mouth by means of its fore paws. In its temper it is generally mild and tractable, but it will not always suffer itself to be handled without resistance, and sometimes bites the hand which attempts to fondle it when not in a humour to be played with. Although a native of the alpine valleys of Chili, and consequently subjected in its own country to the effects of a low temperature of the atmosphere, against which its thick coat affords an admirable protection, it was thought necessary to keep it during the winter in a moderately warm room, and a piece of flannel was even introduced into its sleeping-apartment for its greater comfort. But this indulgence was most pertinaciously rejected, and as often as the flannel was replaced, so often was it dragged by the little animal into the outer compartment of its cage, where it amused itself with pulling it about, rolling it up, and shaking it with its feet and teeth. In other respects it exhibits but little playfulness, and gives few signs of activity; seldom disturbing its usual quietude by any sudden or extraordinary gambols, but occasionally displaying strong symptoms of alarm when startled by any unusual occurrence. A second individual of this interesting species has lately been added to the collection by the kindness of Lady Knighton, in whose possession it had remained twelve months previously to her presenting it to the Society. This specimen is larger in size and rougher in its fur than the one above described; its colour is also less uniformly gray, deriving a somewhat mottled appearance from the numerous small blackish spots which are scattered over the back and sides. It is possible that this may be the Peruvian variety, mentioned in the extract from Schmidtmeyer's 'Travels,' as furnishing a less delicate and valuable fur than the Chilian animal. It is equally good-tempered and mild in its disposition, and, probably in consequence of having been exhibited in a public collection, is much more tame and playful. In its late abode it was frequently suffered to run about the room, when it would show off its agility by leaping to the height of the table. Its food consisted principally of dry herbage, such as hay and clover, on which it appears to have thriven greatly: that of the Society's original specimen has hitherto been chiefly grain of various kinds and succulent roots. When the new-comer was first introduced into Bruton Street, it was placed in the same cage with the other specimen; but the latter appeared by no means disposed to submit to the presence of the intruder; a ferocious kind of scuffling fight immediately ensued between them, and the latter would unquestionably have fallen a victim had it not been rescued from its impending fate: since that time they have inhabited separate cages, placed side by side; and although the open wires would admit of some little familiarity taking place between them, no advances have as yet been made on either side. Such an isolated fact can, of course, have little weight in opposition to the testimony of Molina, that the Chinchilla is fond of company. It is nevertheless a remarkable circumstance, and deserves to be mentioned in illustration of the habits of these animals." It breeds freely in confinement, the oldest pair at present in the Zoological Gardens, Regent's Park, having produced seven young ones.



Chinchilla lanigera.

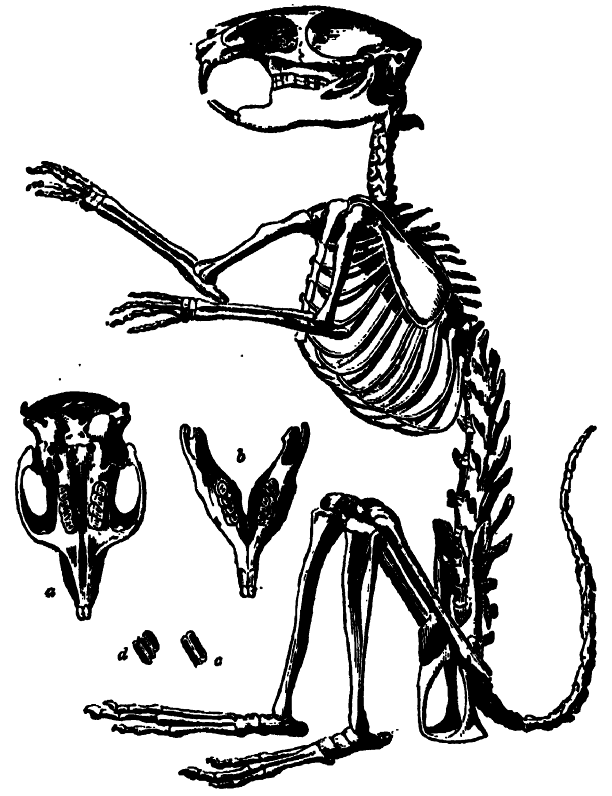
The fur of this species is a considerable article of commerce. In muffs, tippets, linings to cloaks and pelisses, and trimmings for the same, it is sold extensively, and at a comparatively high price. The annual import of the skins of Chinchillas into England in 1851 was 85,000: about 18,000 of these were re-exported.

C. brevicaudata, Waterhouse (*Eriomys Chinchilla*, Lichtenstein and Wagner). Mr. Waterhouse, in his 'Natural History of the Mammalia,' says, "I feel little doubt that further investigation will prove this to be a distinct species from the *C. lanigera*." This species inhabits Peru, and is larger than the last.

Lagostomus. Incisors, $\frac{2}{2}$; molars, $\frac{4-4}{4-4} = 20$.

The incisors are sharpened; the molars each consists of two complete oblique lamellæ, the upper posterior one being trilamellar. Anterior feet 4-toed, the thumb being altogether deficient, the nails small and falcular. Posterior feet 3-toed, the nails produced, straight, and robust. Ears moderate. Tail moderate.

L. trichodactylus, Brookes (*Callomys Viscacia*, Is. Geoffroy and D'Orbigny; *Dipus maximus*, De Blainville). It is La Vizcacha of D'Azara, and the Marmot Diana of Griffiths, translator of Cuvier's 'Animal Kingdom.' The following are the characters as given in Mr. Waterhouse's work:—Body stout; limbs powerful; tarsi long; ear nearly half as long as the head, broad at the base, narrow at the opposite extremity, being distinctly emarginated behind; fur soft and moderately long. General line of the upper parts of the animal gray, somewhat mottled with dusky, and distinctly pencilled with black; the whole of the under parts white or yellow-white; a broad dusky or black band extends on either side, from the muzzle to the back part of the cheek; an equally broad white band crosses the muzzle and terminates on each side beneath the eye, and a third narrow band passes across the forehead, which is of a dusky hue; tail about half the length of the body, for the most part of a dusky brown-blackish colour, and clothed with long hairs on the upper surface.



Skeleton of Marmot Diana (*Lagostomus trichodactylus*).

a, Upper jaw; *b*, lower jaw; *c*, crown of the second molar tooth of the left side of the lower jaw; *d*, crown of the last molar tooth of the right side of the upper jaw.

This animal appears to be the Viscacha described by so many travellers as colonising the vast plains eastward of the great chain of the Andes. Dobrizhoffer, Jolis, D'Azara, Proctor, Head, Miers, and Haigh, all mention it. Captain (now Sir Francis) Head gives a picture of these animals, sitting solemnly at the entrance of their burrows, quite in his peculiar style. Biscacho is the name he assigns to them, and according to his account, the Biscachueras, or Biscacho burrows, which perforate the plains, are terrible traps for the unwary horsemen.

The following extracts are from the accounts of two foreign travellers (whose works are not in the hands of every one) of the habits of this species:—"The Biscacha, called by the Abipones Neheláterek," says Dobrizhoffer in his curious 'Historia de Abiponibus' (Viennæ, 1784), "digs its burrows in the more elevated parts of the plains with so much art, that no aperture is left by which the rain can penetrate; and these burrows are divided into distinct settlements, numerous families inhabiting the same locality. On the surface of the ground are several entrances to the burrows, at which, towards sunset, they are seen seated in crowds, diligently listening for the sound of any person approaching. If everything remains quiet, they seek their food in the obscurity of the night, and commit grievous devastation on the neighbouring fields, devouring both wheat and Indian corn with extreme avidity, and when either is to be had despising grass. For this reason the stations of the Biscachas are rarely to be seen in the desert plains, but indicate with certainty the near neighbourhood of the Spanish settlements. I have often wondered never to have seen the Biscacha in the territories either of the Abipones or the Guaranis, although well supplied with all kinds of crops. They daily heap up, at the entrances of their burrow, dry bones, chips of wood, or whatever other refuse they may meet with, but for what purpose they collect such things it is impossible even to conjecture. The Spanish colonists amuse themselves with hunting them; pouring many buckets of water into their subterraneous retreats, until, to avoid drowning, the animals come forth into the plain, where, no means of escape being afforded them, they are killed with sticks. Their flesh, unless when very old, is not considered despicable even by the Spaniards."

The Abbé Jolis dwelt for twelve years in South America, and made three journeys into the remote districts of the interior. His work, 'Saggio sulla Storia Naturale della Provincia del Granchaco' (Faenza, 1789), is so little known, and his description in some particulars differs so much from that of Dobrizhoffer, that we give Mr. Bennett's translation of it:—"The Biscachas live in society in burrows underground, which they form for themselves, excavating in all directions to the extent of a mile in circumference, with various exits and separate retreats, in which the old live distinct from the younger. The soil in which these are usually made is that which is hard and barren, and destitute of everything, but with bushes (boscaglie) at no great distance, and pasture of tender grass, roots, and the bark of trees. They collect around their retreats bones, dried leaves, and whatever they find in the neighbourhood: if anything is missing in their districts, it is to be found with certainty piled up in these situations the following day. As they are animals that avoid the light, having little power of vision, they are not to be seen in the day-time, unless at dawn, or towards evening after sunset. The night, and especially when the moon shines, is the proper time for seeking their food. Those among the Biscachas which are called Chinchillas, and which may be said to belong to the first species, inhabit only the mountains and cold situations; in size they are like a rabbit, and are clothed with a fine long fur. Their agility is surprising; they are seen leaping from rock to rock as if they had the faculty of flight. The others, indicated above, inhabit the level country in warm situations. . . . Fierce and courageous, they defend themselves with all their might against the dogs, and sometimes even attack the legs of the hunters. I shall speak in my travels, as a fitter place, of the three curious modes in which they are driven out of their retreats; that is to say, with water, with fire, and by rubbing sticks together."

But neither of those authors mentions the somewhat anomalous companions with which the Biscachoes are associated, and we select from the travels of Proctor, Head, Miers, and Haigh, the account of the first-named traveller, which, as Mr. Bennett observes, gives nearly all the particulars which are to be found in the rest. "The whole country, from Buenos Ayres to San Luis de la Punta, is more or less burrowed by an animal between a rabbit and a badger, called the Biscacho, which renders travelling dangerous, particularly by night, their holes being so large and deep that a horse is almost sure to fall if he steps into one of them. The Biscacho never ventures far from its retreat, and is seldom seen till the evening, when it comes out to feed, and hundreds may be observed sporting round their holes and making a noise very similar to the grunting of pigs. Their flesh is much liked by the people, and they are remarkably fat, and on that account, when caught at any distance from their holes, are easily run down; they will however defend themselves from a dog a considerable time. The holes of these animals are also inhabited by vast numbers of small owls, which sit during the day gazing at the passing travellers, and making a very ludicrous appearance. The parts of the road most frequented by the Biscacho are generally overrun by a species of small wild melon, bitter to the taste; whether it thrives particularly on the manure of the animal, or whether the Biscacho chooses his hole nearer this running plant, does not seem to have been ascertained."

The following account of the habits of this creature, from Mr. Darwin's interesting journal, is one of the most recent contributions published on this subject:—"The Viscacha is well known to form a prominent feature in the zoology of the Pampas. It is found as far south as the Rio Negro, in lat. 41°, but not beyond. It cannot, like the Agouti (*Dolichotis Patachonica*), subsist on the gravelly and desert plains of Patagonia, but prefers a clayey or sandy soil, which produces a different and more abundant vegetation. Near Mendoza, at the foot of the Cordillera, it occurs in close neighbourhood with the allied alpine species. It is a very curious circumstance in its geographical distribution that it has never been seen, fortunately for the inhabitants, in Banda Oriental, to the eastward of the river Uruguay; yet in that province there are plains which appear admirably adapted to its habits. That river has formed an insuperable obstacle to its migration, although the broader barrier of the Parana has been passed; and the Viscacha is common in Entre Rios (the province between the two rivers), directly on the opposite shore of the Uruguay. Near Buenos Ayres these animals are exceedingly common. Their most favourite resort appears to be those parts of the plain which, during one-half of the year, are covered with great thistles to the exclusion of other plants. The Guachos affirm that it lives on roots, which, from the great strength of its gnawing teeth and the kind of localities frequented by it, seems probable. As in the case of the rabbit, a few holes are commonly placed together. In the evening the Viscachas come out in numbers, and there quietly sit on their haunches. They are at such times very tame, and a man on horseback passing by seems only to present an object for their grave contemplation. They do not wander far from their burrows. They run very awkwardly, and when hurrying out of danger, from their elevated tails and short front legs, much resemble great rats. Their flesh when cooked is very white and good, but it is seldom used. The Viscacha has one very singular habit, namely, dragging every hard object to the mouth of its burrow. Around each group of holes many bones of cattle, stones, thistle-stalks, hard clumps of earth, dry dung, &c., are collected into a heap, which frequently amounts to as much as a wheelbarrow would contain. I was credibly informed that a gentleman, when riding in a dark night, dropped his watch; he returned in the morning, and by searching in the neighbourhood of every Viscacha hole on the line of road, as he expected, soon found it. This habit of picking up whatever may be lying on the ground anywhere near its habitation must cost much trouble.

For what purpose it is done I am quite unable to form even the most remote conjecture; it cannot be for defence, because the rubbish is chiefly placed above the mouth of the burrow, which enters the ground at a very small inclination."

CHIOCOCCA (from χιὼν and κόκκος), a genus of plants belonging to the natural order *Cinchonaceæ.* Calyx with an oval tube and an acutely 5-toothed permanent limb. Corolla funnel-shaped, with an obconical tube or throat, and five acute lobes. Stamens with the filaments hardly adnate to the bottom of the corolla, downy, and shorter than the anthers, which are inclosed and linear. Style rather clavate at the apex, entire or slightly 2-lobed. Berry somewhat didymous, compressed, crowned by the teeth of the calyx, containing two chartaceous 1-seeded pyrenæ. Seeds pendulous. Embryo with a long superior radicle. Albumen cartilaginous. Shrubs generally with a somewhat climbing habit. Leaves opposite, ovate or oblong acute, glabrous. Stipules broad at the base, permanent, more or less apiculated. Racemes axillary, opposite, simple or panicled. Flowers pedicellate, of a yellowish-white colour. Roots emetic and alexiteric.

C. racemosa, Racemose Snow-Berry, has oval leaves acuminated at both ends, smooth; stipules broad at the base, and apiculated by a long point at the apex; filaments of stamens downy. It is a native of the West Indian Islands and Carthagena, on hills. It is a very variable shrub. The corollas at first are white and scentless, but at length become yellowish and sweet-scented. The berries are snow-white, hence the English name. The root has an acid bitter taste, and has long been used as a strong resolutive or attenuant; it is administered in obstinate rheumatisms, and is also an excellent emetic. This is a plant commonly cultivated in gardens, and there are several varieties of it.

C. densiflora, Dense-Flowered Snow-Berry, has ovate rather coriaceous leaves, many-flowered racemes, the corolla much longer than the calyx, the filaments densely-bearded. It is a native of Brazil, in woods at Almeida and Serradas, on the mountains of Bahia, and at the port of St. Catherine.

C. anguifuga, Anguifuge Snow-Berry, has ovate acuminated leaves; stipules very broad, short, each ending in a short point; racemes panicled; corolla not quite three times longer than the calycine teeth. It is a native of Brazil in woods, French Guyana, Trinidad, Peru, Cuba, and on the Spanish Main. Both this and the former species are used in Brazil as a certain remedy for serpent bites. An infusion of the bark produces the most violent purgative and emetic effects.

C. odorata, Sweet-Scented Snow-Berry, has broad oval leaves, rather coriaceous, very blunt, acute at the base, and running down the short petioles; peduncles axillary, solitary; 3-4-flowered corolla, with a bearded throat. It is a native of Elizabeth Island, one of the Society Islands. The flowers are described as smelling like cowslips.

C. barbata, Bearded Flowered Snow-Berry, has oval leaves, acute at the base, and tapering into short petioles, acuminated and obtuse at the apex; peduncles axillary, solitary; 1-3-flowered; corolla with a bearded throat; 5-cleft. It is a native of the Society and Friendly Islands.

C. Javana, Java Snow-Berry, is a parasitical shrub, with oblong lanceolate leaves, acuminated at both ends, glabrous, velvety, and shining above; corymbs terminal, trichotomous. This is a native of Java, on the mountains, upon trees.

All the species of *Chiococca* grow best in a mixture of loam, peat, and sand, and strike freely in sand under a hand-glass.

CHIOLITE, a Mineral found in Siberia. It has a hardness=3·5, and a specific gravity=2·6 to 2·77. It is near *Cryolite* in composition and characters, and appears to be a fluoride of aluminum and sodium.

CHIO'NEA (Dalman), a genus of Dipterous Insects belonging to the section *Tipulariæ terricolæ.*

One species of this genus is remarkable both in its structure and habits. It is less than half an inch in length; the head is of a brownish-yellow colour; the thorax and abdomen are ashy-brown; the latter is of an oval form and rather hairy; the legs are very long, rather thick and covered with hairs, not unlike the legs of a spider, and of a yellowish colour. It is perfectly destitute of wings, and is found upon the snow in the woods of Sweden throughout the winter. The generic characters are:—Body apterous; joints of the palpi nearly equal; antennæ setaceous, 10-jointed, and covered with fine hairs at the extremity; the abdomen of the male terminated by a forceps-like appendage composed of two horizontal jointed processes, and that of the female is terminated by a boring instrument, or ovipositor, consisting of two valvules, placed one upon the other, of which the upper one is the longer, and composed of two plates.

There is another insect which, though it belongs to a different order (*Neuroptera*), resembles this species in its habits of appearing during the winter, and crawling upon the snow, as well as in being apterous, a character which is of rare occurrence in either tribe. [Boreus.]

Two other species of *Chionea* are given in the 'British Museum Catalogue,' both of them inhabitants of North America.

CHIROCEPHALUS, a genus of Entomostracous *Crustacea* belonging to the division *Branchiopoda*, the order *Phyllopoda*, and the family *Branchipodidæ.* In this family two British genera are included—*Artemia* [Branchiopoda] and *Chirocephalus.* *Artemia* is distinguished from the latter by having the caudal segment of the body simply bilobed, and not divided into plates, and has no appendages at the base of the cephalic horns, which are characteristic of *Chirocephalus.* The following are the characters of *Chirocephalus*:—Abdomen large, consisting of nine divisions, and terminated by two well-developed caudal plates or lamellar appendages; cephalic horns of a cylindrical shape, and furnished with fan-shaped and digitiform appendages in the male.

C. diaphanus is the only species. It was apparently first noticed by Linnæus, and called by him *Cancer stagnalis.*

The following synonyms from Dr. Baird's 'History of the British Entomostracous Crustacea,' will give some idea of the history of this curious animal, as of the interest it has created:—

Chirocephalus diaphanus, Prevost, 'Journ. de Phys.' 1803; Jurine, 'Hist. Monoc.'

Branchipus Prevostii, Fischer, 'Bull. Soc. Imp. Nat.' Moscow, 1834.

Chirocephalus Prevostii, Thompson, 'Zool. Researches,' 1834.

Branchipus Chirocephalus, Guerin, 'Icon. Reg. An. Crust.'

Branchipus diaphanus, Milne-Edwards, 'Hist. Crustaceæ.'

Branchipus paludosus, Desmarest, 'Consid. gên. Crust.'; Lamarck, 'Hist. An. s. Vert.,' 2nd ed.

Cancer stagnalis (Linn. ?), 'Linn. Trans.,' vol. i.

Cancer paludosus (?), Müller, 'Zool. Dan. Herbst. Krabben.'

Branchipus stagnalis, Milne-Edwards, Cuv. 'Règne Animal,' edit. Crochart.

Ino piscina, Schrank, 'Faun. Boic.,' 1803.

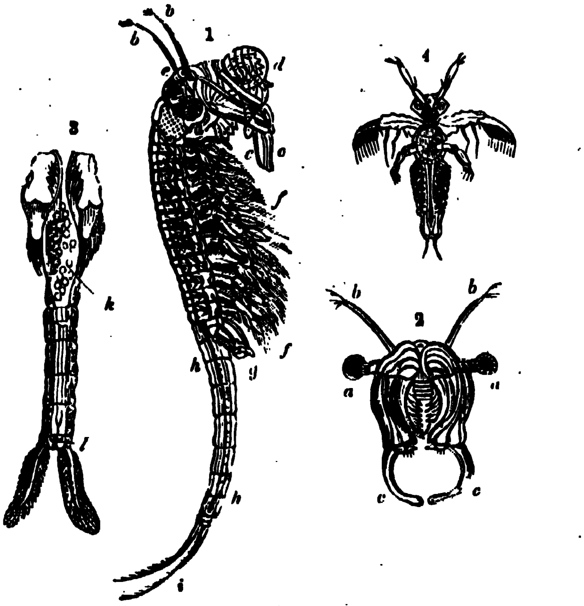
Marteau d'Eau douce, Duchesne, 'Man. du Naturaliste.'

Remarkable Aquatic Insect, King, 'Phil. Trans.,' 1762.

Squilla lacustris minima, Petiver, 'Gazoph. Nat.,' 1709.

The following is Dr. Baird's description of the species:—

"When full grown it is upwards of an inch in length, slender, of a cylindrical form, and nearly perfectly transparent. The male is more so than the female, but with a slight reddish tinge throughout. The tail is of a bright-red; the large basal joint of the prehensile antennæ of a beautiful transparent bluish-green colour, tipped at the extremity, where the second joint arises, with a fine red hue. The back of the female is of a blue colour; and the ovary, when full of ova, of a reddish-brown."



Chirocephalus diaphanus.

1, Male, magnified; *a a*, composite or network eyes; *b b*, antennæ; *c c*, mandibuliform horns; *d*, proboscidiform moveable tentacula, rolled spirally; *e*, simple rudimentary eye; *f f*, leaf-like natatory feet or oars; *g*, male organs; *h h*, tail; *i*, terminating filaments; 2, front view of the head; 3, tail of the female; *k*, egg-pouch; *l*, female organ; 4, a young *Chirocephalus* after the first moult.

This beautiful little creature is not often met with, and when found is always an inhabitant of dirty, stagnant water. The places in which it is found have also another peculiarity—that of being dried up for the greater part of the year. Thus, the most common places for it are ditches by road-sides, and cart-wheel ruts. Several localities have been given for it in England; the most common is that of Blackheath, where in a few of the pools by the roadside, which are mostly dried up during the greater part of the year, it is very abundant after rain. It has also been found near Epping, near Brighton, near Bristol, near Hammersmith, and in Devonshire. In the description given of them by King in the 'Philosophical Transactions' for 1767, they were found in a ditch of standing water near Norwich. "They were discovered," says Mr. King, "by a poor man, now dead, whose genius was very extraordinary, and much superior to what is usually found in his rank. He was indefatigable in his searches after everything curious, and, without ever having had any advantages of education, had acquired a degree of knowledge by no means contemptible."

Schœffer discovered them in a pool of water near Ratisbon. Prevost found his specimens at Montaubon, and at Jurine's request sent some ova in moist paper to Geneva, where Jurine succeeded in hatching them and making those observations which are published in his 'Monocles qui se trouvent à Genève.' Dr. Baird says, "It is rarely to be met with in this country, compared with the *Daphniœ* and many other *Entomostraca;* the only place near London where I have met with it being on Blackheath. They swim upon their backs, and in fine warm weather, when the sun is not too strong, they may be seen balancing themselves, as it were, near the surface by means of their branchial feet, which are in constant motion. On the least disturbance, however, they strike the water rapidly with their tail from right to left, and dart away like a fish, and hasten to conceal themselves by diving into the soft mud or amongst the weeds at the bottom of the pool. They are nearly transparent, and are of a very light reddish colour, with a slight tinge of blue on some parts. 'When placed in a glass of clear water,' says Prevost, 'the elegance of its form, the ease and softness of its movements, its silvery transparency, or its brilliant colours, its large black eyes, the small spot which it carries on its head, the crown of the male—are a beautiful sight, which the most indifferent observer cannot see without pleasure.'

"It is certainly the most beautiful and elegant of all the *Entomostraca.* The male is especially beautiful. The uninterrupted undulatory wavy motion of its graceful branchial feet, slightly tinged as they are with a light reddish hue, the brilliant mixture of transparent bluish-green and bright-red of its prehensile antennæ, and its bright-red tail, with the beautifully plumose setæ springing from it, render it really exceedingly attractive to the view.

"The undulatory motion of its branchial feet serves another purpose in addition to that of keeping the animal suspended in the water. The thorax or body of the animal has been described, when floating on its back, as like the cavity of a little boat, the feet representing oars. When these are in motion, they cause the water contained in this boat-like cavity to be compressed, and to mount up as along a canal, carrying in the current the particles destined for its food towards the mouth. It seems to be constantly, when in this position, employed in swallowing and digesting its food, its masticatory organs being in perpetual motion. Shaw imagined this little creature to be a fierce and voracious beast of prey, but it is not so; he was misled in so thinking by not understanding the true nature of its prehensile antennæ. These he imagined were organs for seizing its victims and crushing them to death, though he candidly admits that he never saw them attack other animals, and even says that he has seen them succumb to the assaults of the *Cypris.* According to Prevost, they live upon dead animal or vegetable matter, but they have apparently little taste, for they swallow every sort of thing that comes in their way, however hurtful it may be. Schœffer says that he found great difficulty in keeping the *Branchipus* alive after having been taken out of the water in which they were found, and also says that they are incapable of bearing any degree of cold. Jurine, however, found no difficulty in hatching the ova of the *Chirocephalus* sent to him by Prevost, and keeping the animals so hatched till they reached maturity; and Shaw distinctly asserts that he has found them in this country, in shallow pools, in the months of December and January, even after pretty sharp frosts, as lively almost as in spring or summer. I have always found them in the months of October, November, and December, and even after frosts of short continuance though of considerable severity. In general they have been very short-lived after being removed from their native habitat, but I have been able to hatch the young and watch their progress to maturity. Though they do not appear destructive to other animals, they fall an easy prey themselves to various enemies. Frogs, salamanders, the larvæ of the *Dytesci,* the *Cyprides,* and other such inhabitants of the water, kill them in vast numbers; and they seem besides, according to Prevost, to be specially infested by a species of *Vorticella,* or wheel-animalcule, which attaches itself to the body of the animal in great numbers, and would very soon, were it not for their moulting frequently, completely destroy it. I have found them very liable to a peculiar disease which seems very frequently to terminate fatally. It attacks their body near the external ovary, the lower part of the abdomen, &c., and the branchial feet are not exempt from it. It consists of a white growth, composed of a fatty sort of substance, and when once this appears, the poor animal almost always soon after dies."

After impregnation "the ova appears at first as small white spherical bodies lying in the internal ovary, which stretches along the abdomen, and then passing from it into the external ovary already described. When the proper time arrives the mother deposits these ova loose in the water, the ovary opening at the point, and the eggs being thrown out by a sudden jerk to the number of 10 or 12 very rapidly. The whole process of laying lasts several hours, sometimes, according to Prevost for a whole day, and the number of ova excluded vary from 1 to 400. At first the egg is yellowish spherical, beset all round with short setæ, but when it has been for a short time exposed to the action of the air and the water, it assumes an irregular hexagonal figure and a greenish hue. In about a fortnight or so the egg is hatched and the young one issues forth, but very unlike its parent. It consists of two nearly equal oval portions, head and body."

According to the recent observations of Dr. Zenker ('Physiological Remarks on the Daphnidæ,' translated in vol i. of 'Microscopical Journal') and others, it appears that the female *Daphnidæ* have the power of producing eggs which are fertile without access to the male. This is what occurs in some of the *Aphides* for a given number of generations. In the *Daphnidæ* it appears to be without limit. This reproduction from unimpregnated ova is quite analogous to the process of gemmation amongst the lower animals. The great difference is that it takes place from the ovary and not from some more general tissue of the body. In the *Daphnidæ,* however, ova are produced after impregnation, which differ from the other in being enveloped in a fine corneous saddle-shaped shell which is called an 'ephippium,' and such ova, as they are now known to occur in other animals, are called 'ephippian ova.' Mr. Huxley however, who has described them in *Lacinularia socialis,* a species of *Rotifera,* says they "probably do not require fecundation, and are thence to be considered as a mode of asexual reproduction."

In reference to this curious subject, Mr. Busk has added the following note to Zenker's remarks on *Daphnidæ,* in the first volume of the 'Microscopical Journal':—

"The number of males is very considerable, and pretty nearly equal to that of the females at all times of the year. This fact seems to afford a curious confirmation to Dr. Zenker's opinion, that the chief object of male impregnation is the production of ephippian, or winter ova. In the case of *Chirocephalus* this provision becomes repeatedly necessary during the year, and not towards winter only; for it is a remarkable fact, on Blackheath at all events, that the *Chirocephalus* is never found in any of the several ponds on the heath, except in those which dry up completely, at least once, but in some years several times, or for the whole summer continuously. The ponds inhabited by the *Chirocephalus,* in fact, are merely pools formed by the drainage from the roads. Now, it is manifest under these circumstances that were not provision made by the formation of winter ova, or ova having a thick double coat, for the revival of the race after the drying up of their habitation, it would become extinct. We accordingly find that such provision is made in the numerous males at all times present.

"The extraordinary power possessed by the ova of the *Chirocephalus* of resistance to the effects of desiccation is very remarkable, as is also the readiness and rapidity with which they are developed when again subjected to the influence of water. If the basin of a small pool which has been dry and even dusty for months becomes filled after a few days' rain, the water will be found swarming with myriads of *Chirocephali* in about ten days or a fortnight; or if a piece of the dried bottom of such a pool be placed in a pailful of water, numerous *Chirocephali* will be hatched from it in the same time. The reason for this curious arrangement with respect to the *Chirocephali* is obvious enough. These delicate creatures, themselves vegetable feeders, are the prey of innumerable enemies; among the chief of which are the larvæ of *Dysticus,* and of Dragon-Flies, &c. In ponds which never dry up, these voracious enemies have time and opportunity to destroy the whole race of *Chirocephali;* but in the favourite haunts of the latter, their enemies not being able to survive the drying up of the water, are cleared off on each such occasion, and the *Chirocephali* being rapidly hatched, have, as a race, time to propagate and deposit their posterity in safety for another resurrection."

Another point of interest with regard to *Chirocephalus* is, that it affords an instance of the nearest living type, to the extinct family of *Trilobites.* [TRILOBITES.] Professor Burmeister, at the conclusion of his laborious investigation into the structure and affinities of this family, in his work on the 'Organisation of Trilobites' (translated into English and published by the Ray Society), says, "The *Trilobites* were a peculiar family of *Crustacea,* nearly allied to the existing *Phyllopoda,* approaching this latter family most nearly in its genus *Branchipus* (*Chirocephalus*), and forming a link connecting the *Phyllopoda* with the *Pœcilopoda.*"

CHIRO'NOMUS, a genus of Dipterous Insects of the family *Tipulidæ.* This genus was established by Meigen, and is principally distinguished by the following characters:—Fourth joint of the palpus longer than the rest; antennæ 13-jointed, in the male, and furnished with long hairs; the antennæ of the female are 6-jointed, and the hairs are short; the anterior legs are inserted at some distance from the others, and the anterior tarsi are generally very long; the wings when closed lie parallel, and they have three posterior cells; the body is long, slender, and hairy.

Mr. Stephens, in his 'Catalogue of British Insects,' enumerates upwards of eighty species of this genus: they are all of small size, frequent marshy situations, and very much resemble gnats. The worm known to anglers by the name of Blood-Worm is the larva of one of the species of this genus—the *Chironomus plumosus.* This worm is about half an inch in length; the body consists of numerous segments, and is furnished at the tail with several appendages which constitute the breathing apparatus. It is seen during the summer months on the mud near the edges of ponds and ditches; when thus seen however it is only shifting from one place to another, its natural locality being in the mud, where it may generally be found in great numbers, living for the most part under water. This larva is much sought after and devoured by birds and fishes; but during the summer of 1836 we discovered that it had a very formidable enemy in an insect of its own order. A fly, which closely resembled the house-fly, was observed in great abundance on the mud which had just been left by the retiring water, and we found them assembled in little groups of five or six, in the act of extracting the blood-worms from their holes, using the proboscis for this purpose: but no sooner was the worm fairly dislodged than a battle ensued, for each apparently wished to have the worm to itself; those that kept possession sucked out the fluids from the worm.

The pupa is of a brownish colour; the body is cylindrical, the head, thorax, wings, and legs are inclosed in separate sheaths, and, with the exception of the two fore legs, lie in a close and compact mass; the fore legs, covered by their sheaths, project from each side of the thorax. In this as well as in the larva state, the animal lives in the water. The breathing apparatus consists of two appendages, one on each side of the thorax, and each is composed of five branches which spring from a common centre.

When the insect is ready to quit its pupa case, it gains the surface of the water, and there remains suspended for some little time with the disc of the thorax slightly protruded; this part bursts down the middle, and the insect, which is hairy, and hence does not easily wet, places its feet upon the surface of the water, where it floats (if the weather be calm) with the greatest safety. We observed, upon taking one upon our finger, that the wings are at first opaque and white, and filled with a fluid; but in a minute this fluid was expelled, and the sides of the wings collapsed and became transparent. The fluid thus ejected we perceived on our finger beneath the insect, but could not ascertain from what part of the wing or body it made its escape.

Discussions have arisen on the means which this animal possesses of suspending itself at the surface of the water without motion, its specific gravity being supposed to be greater than water.

Messrs. Kirby and Spence account for it by a kind of propelling power which the centre of the thorax possesses, and state that this part being thus protruded and drying, the attraction of the air to the dry portion of the thorax is sufficient to overcome the slight difference in the specific gravity between the animal and the element; but it is further stated that if a drop of water fall upon the insect at this time it will immediately sink.

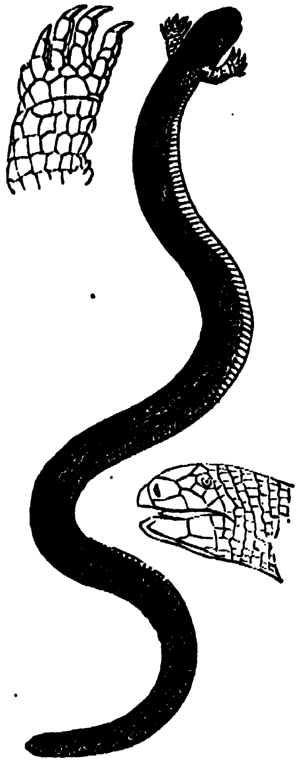
We have kept these insects in a glass jar for the purpose of observing their habits, and are very much inclined to doubt that the specific gravity of the pupa is greater than that of the water, at the time just previous to the transformation from pupa to the imago state. Indeed at this time it appeared that they could not keep from the surface, unless they were in motion. Whenever we approached the jar, being at the top, they immediately descended by a quick zigzag movement of the body; but upon our remaining quiet for a moment they ceased all motion and rose to the surface again. We imagine that at this time the animal within having become partially disengaged from the pupa case, the space between the two is filled with air, that this would be sufficient to overcome the difference of specific gravity between the animal and the water, and that there would most probably be more air in the region of the thorax than elsewhere; and hence this part is protruded from the water.

The perfect insect is of a pale-ash colour, and is a little larger than the common gnat, which it resembles. This, as well as others of the genus, is remarkable for its habit of carrying the two fore legs in a horizontal position; they project in front, and might be mistaken for antennæ; these latter organs however are very beautiful, and in the males resemble little plumes.

CHI'ROTES, a genus of Saurians separated by Cuvier, and, according to him, resembling the *Chalcides* in their verticillated scales, and the *Amphisbænæ* still more in the obtuse form of their head; but distinguished from the first by their want of posterior feet, and from the last by their possession of anterior limbs. The same author adds, in a note to the last edition of the 'Règne Animal,' that the genera which terminate this order of Saurians are interposed in various manners between the ordinary Saurians and the genera which are placed at the head of the order Ophidians to such a point, that many naturalists are now of opinion that the two orders ought no longer to be separated, or rather that one order should be established, comprising on the one part the Saurians, with the exception of the *Crocodilidæ*, and on the other the Ophidians of the family *Anguidæ*. But he observes that there exist, among the fossil forms of the ancient calcareous beds, two very extraordinary genera (*Ichthyosaurus* and *Plesiosaurus*), which, with the head and trunk of a Saurian, have feet attached to short limbs, and formed of a multitude of small articulations conjoined so as to form a kind of paddle or fin, like the anterior paddles or fin-feet of whales. These ought, he adds, to form a very distinct family. In their osteology they approach the Saurians, properly so called, much nearer than the Crocodiles, with which Fitzinger associates them in his family *Loricata;* though in the fossils there is no trace either of scales or of the tongue, the two parts on which the characters of the *Loricata* rest.

These Bimanous Reptiles, as Cuvier terms them, include, according to him, but one species, which is a native of Mexico. This is the Bimane Cannelé (*Chirotes canaliculatus*) of Cuvier, Bipède Cannelé of Lacépède, *Chamæsaura propus* of Schneider, and *Lacerta lumbricoides* of Shaw. The animal has two short feet with four toes on each (and the vestige of a fifth) sufficiently organised internally, and attached by means of scapulæ, clavicles, and a small sternum; but the head, the vertebræ, and, in short, all the rest of the skeleton resemble that of the *Amphisbænæ*. Dr. J. E. Gray refers *Chirotes* to a third family of the Amphisbænians which he calls *Chirotidæ*.

Chirotes canaliculatus (*C. lumbricoides*, Fleming; *C. Mexicanus*, Bory; *Bipes canaliculatus*, Bonnaterre; *Chamæsaurus propus*, Schultz; *Chalcides propus*, Daudin), is about the size of a human little finger, and is from eight to ten inches long. It is of a flesh-colour, and covered with about 220 demi-rings on the back, and as many under the belly, which meet, in alternating, on the side. The tongue is but little extensile, and is terminated by two small horny points. The eye is very minute. The tympanum is covered with skin and invisible externally. Above the vent are two lines of pores. It is a native of South America.



Chirotes canaliculatus.

CHI'RUS, a genus of Fishes belonging to the section *Acanthopterygii* and the family *Gobiodæ*. The species of this genus have the body considerably elongated, furnished with ciliated scales, and the mouth not deeply cleft; the teeth are small and conical; but the most remarkable character consists in the body being furnished with several longitudinal lines of pores, similar to the ordinary lateral line. Some of the species have appendages over the eyes, as observed in the Blennies; their ventral fins have each five soft rays: the spines of the dorsal fin are slender, and this fin extends nearly the whole length of the back.

Cuvier says that it is with hesitation that he places this genus with the family above mentioned, and that it will probably one day form the type of a separate family. All the species as yet discovered inhabit the seas of Kamtchatka—they are included in the genus *Labrax* by Pallas, who describes several of the species in the 'Memoirs of the Academy of St. Petersburgh,' vol. ii.

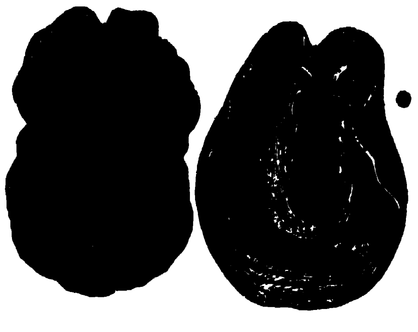
CHISMOBRANCHIA'TA, an order of *Mollusca*, forming, in De Blainville's system, the second order of his second sub-class, *Paracephalophora Monoica*. The following is his definition of the order:—Organs of respiration aquatic, branchial or pectinated, situated at the anterior part of the back, in a large cavity communicating with the ambient fluid by a wide oblique anterior slit. Mouth toothless, but provided with a long lingual riband-like organ. Shell either none, or internal, or external, very much depressed, with a very large entire aperture, and without any pillar (columella).

This definition is incorrect, in so far as it states that in some instances there is no shell; for *Coriocella*, the only genus described by De Blainville as being without any shell, has a horny one, as Cuvier observes, though it is very delicate and flexible and nearly membranous. Cuvier, who places three of the genera, *Sigaretus*, *Coriocella*, and *Cryptostoma*, under his *Capuloides*, a family of his order *Gasteropoda pectinibranchiata*, observes that De Blainville places the greater part of the *Capuloides* under his non-symmetrical

Hermaphrodite paracephalophora, or Calyptracians; but that they appear to him (Cuvier) to be all diœcious.

The geographical distribution of this order, which, according to De Blainville, is marine and probably herbivorous, is wide.

Coriocella.—Body elliptical, very much depressed, having the borders of the mantle very delicate, notched in front, and spreading out very largely on all sides. Foot oval, very small. Head scarcely distinct; two tentacula hidden under the shield of some size, but short and contractile. Eyes at the external base of the tentacula. Back somewhat rounded, and, according to De Blainville—but this as we have already seen is an error—without any shell, external or internal.



Coriocella nigra.

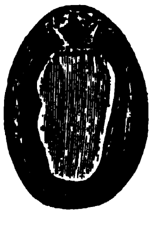
C. nigra, Blainville. The only species of the genus, and described by De Blainville from a specimen in his collection. Locality, seas of Mauritius. Cuvier places this and the two following genera under his *Gasteropoda pectinibranchiata.*

Sigaretus.—Shell more or less thick, flattened, with an ample and round aperture and but little spire, the whorls of which increase very suddenly; and enveloped during life in a spongy shield, which considerably encompasses its borders as well as the foot, and which is the true mantle. In front of this mantle there is a notch and a demi-canal, which serve to conduct the water into the branchial cavity. The tentacula are conical, and the eyes are placed at their external base. The male organ, according to Cuvier, is very large.

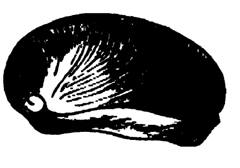
De Blainville thus subdivides the genus:—

a. Species with a very delicate and smooth shell.

Example, *S. convexus.*



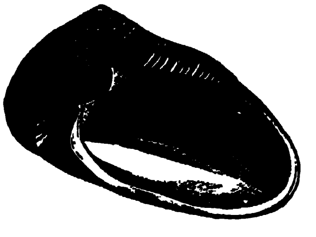
Sigaretus convexus, seen from below.



Sigaretus convexus, side view.

b. Species with a thick and solid shell.

Example, *S. haliotoideus.*



Sigaretus haliotoideus.

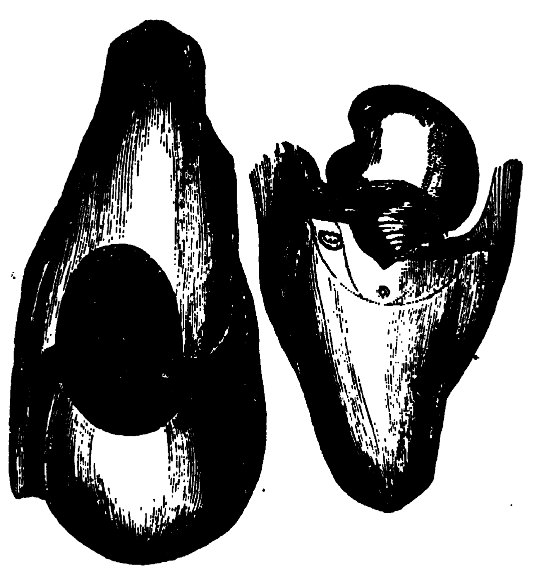
The species of *Sigaretus* have been found at depths varying from 5 to 15 fathoms on sandy bottoms.

Fossil Sigareti.

Defrance enumerates three fossil species, one from the Plaisantin, one from Grignon, and another from the environs of Bordeaux. G. B. Sowerby says that the fossil species are few and rare, and that they occur in the London Clay at Barton, and in the contemporaneous formations in France and Italy. The species in the Calcaire Grossier at Grignon, he adds, has a small umbilicus. Deshayes in his 'Tables' gives eleven living species and four fossil (tertiary); one, *S. depressus*, living in the seas of the Molucca Islands. The fossils occur in the Pliocene, Miocene, and Eocene periods of Lyell. *S. excavatus* is found in the Crag.

Cryptostoma.—Shell very like that of *Sigaretus*, carried with the head and abdomen, which it covers, upon a foot four times its size, cut almost squarely behind, and which produces anteriorly a fleshy and oblong part, which makes nearly one-half of the mass. The animal itself has a flat head, two tentacula, and a large pectinated branchia on the plafond of its dorsal cavity. The male organ is placed under the right tentaculum.

Example, *C. Leachii.*



Cryptostoma Leachii.

Oxynöe.—Body gasteropod, with a large dorsal shell, anterior, bulliform, and with a simple spire. Foot narrow. Branchiæ marginal, striated transversely. Mantle widened into two lateral wings. Tentacula two, not retractile.

Example, *O. olivacea.*

Velutina.—Animal oval, sufficiently protuberant (bombé), hardly spiral; border of the mantle simple anteriorly, and double for the whole of its circumference; the internal lip thickest and tentacular. Foot thick. Tentacula large, obconical, distant, with a small frontal veil between them. Eyes black, sessile at the external side of the base of the tentacula. Mouth large, at the extremity of a sort of muzzle. Respiratory cavity large, without any trace of a tube, and containing two unequal pectinated branchiæ; orifice of the ovary at the base of the male organ, situated at the root of the right tentaculum. Muscular attachment of a horse-shoe shape, very slight behind and open before. Shell external with an epidermis, patelliform, with a small lateral spire, and without a columella. Aperture large, the edges almost continuous, and sharp: the right border united to the left by a lamellar calcareous deposit.

Example, *V. capuloidea* (*Helix lævigata*. Linn.). [VELUTINIDÆ.]

Velutina capuloidea.

CHITON. [CHITONIDÆ.]

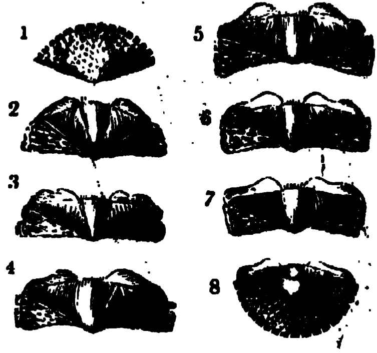
CHITONELLUS. [CHITONIDÆ.]

CHITONIDÆ, a natural family of Gasteropodous *Mollusca*, affording the only known instance of a protecting shell formed of many portions, or, as they have been somewhat incorrectly termed, valves, often in contact and overlapping each other, but never truly articulated. The following cut will give some idea of the structure of this shelly covering.

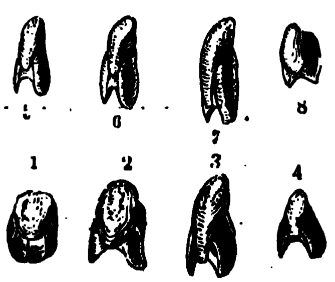
These plates are bound together by a coriaceous border, which, as we shall presently see, is either plain or beset with bristles, spines, &c.

The early naturalists took these shells for the peculiar armour of certain serpents, a conclusion to which they were doubtless helped by the love of the marvellous, so strongly shown in the accounts of the older travellers. By degrees the true condition of these mollusks became better known; and the opposite opinions of Linnæus and Adanson divided the naturalists of their age. The former arranged these shells among his Multivalves, a class entirely artificial, and like all artificial classifications comprising the most heterogeneous forms. Adanson, on the contrary, took nature for his guide, and carefully observing the animal itself, while he regarded the shell as of comparatively small importance, placed *Patella* and *Chiton* side by side in his method. But the Linnæan school long reigned paramount; and Adanson's labours were comparatively forgotten, when Cuvier began to reform the crude state in which he found the *Mollusca*, and Lamarck and others aided in the work. Cuvier, who made anatomical investigation the basis of his opinions, at once pronounced in favour of Adanson. Lamarck afterwards adopted the same conclusion, but not till he had previously placed the Chitons at the end of the

Acephalous Mollusks, between *Fistulana* and *Balanus*. Poli, in his magnificent work on the 'Testacea utriusque Siciliæ,' in giving the anatomy of a Mediterranean species, became a valuable ally; for although he still retained Linné's class of Multivalves, and although in his anatomical details he said nothing of the nervous system, a branch of animal organisation essentially necessary to be known for assigning an animal its true place, he demonstrated enough clearly to show that the *Chiton* bore no relation to the other Multivalves of Linnæus. M. De Blainville however, resting upon the generative faculty of the Chitons, proposed, in opposition to these views of Cuvier and Lamarck, which had been adopted by almost all zoologists, to form a sub-type of Mollusks under the name of *Malentozoaria*, in which each of the Linnæan genera *Lepas* and *Chiton* constitutes a class; the first the Lepadians, or *Lepadicea*, the second the Polyplaxiphores, or *Polyplaxiphora*. These almost singular views of De Blainville have not prevailed among zoologists; and Cuvier, in the last edition of the 'Règne Animal,' arranges the Chitons at the side of the *Patellæ*, forming from these two genera his small family of Cyclobranchians.



Shelly plates or valves of *Chiton*.



Shelly plates or valves of *Chitonellus*.

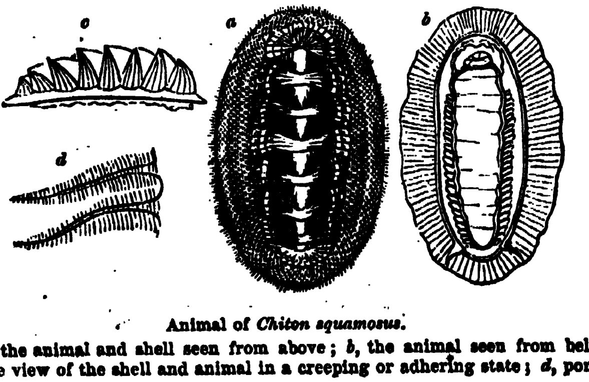
Deshayes, in the article 'Oscabrion,' in the 'Encyclopédie Méthodique,' enters at large into the organisation of the Chitons, and discusses with much learning and acuteness the conflicting opinions of Cuvier and De Blainville.

The following is a summary of the structure of this family:—

Digestive Organs.—No projecting head, in which the Chitons resemble the Phyllidians. No tentacula, which are replaced by a kind of veil which surrounds the mouth. Eyes, as in many other Mollusks, the *Pteropoda* for example, wanting. Mouth and œsophagus furnished with a very long tongue rolled spirally and armed with horny teeth, a good figure of which is given by Poli. Loven has pointed out that the teeth, especially the central one on the lingual riband, are of great importance in determining the species. Stomach intestine, and liver like those of the other Gasteropods. Vent at the posterior extremity of the body, as in the Phyllidians, *Doris*, &c.

Respiratory and Circulating Organs.—The branchiæ of the Chitons consist of a range of small triangular leaflets placed, as in the *Patella* and *Phyllidia*, in the furrow which separates the foot from the mantle. The number and extent of the branchial laminæ are of importance in determining the species. The heart is situated posteriorly in the mesial and dorsal line; it is symmetrical, and composed of a single ventricle and two auricles.

Their organs of generation are symmetrical, and repeated on each side of the mesial line, and there are a pair of sexual orifices.



Animal of *Chiton squamosus*.

a, the animal and shell seen from above; *b*, the animal seen from below; *c*, side view of the shell and animal in a creeping or adhering state; *d*, portion of branchiæ magnified.

The nervous system consists of what may be termed a complete œsophagean ring, and of various branches, which are given off divergingly towards the several organs.

The locomotive organs consist of an oval foot, more or less wide, according to the species, and extends the whole length of the animal.

The shell is composed of eight narrow, transverse, calcareous pieces, overlapping each other, and strongly implanted on each side in a thick and fibrous border of the mantle, which surrounds the whole body, and is sometimes, as we have observed, naked, but more generally covered with small scales, spines, or hairs. These pieces are not immoveable, as the animal can roll itself up or stretch itself out again for the purpose of progression or adhesion. To work this machinery, there are three muscles given off from the first piece to the second, three others given off from the second to the third, and so on throughout, so as to make the mechanism of this scale-armour complete. One of these muscles occupies the mesial and dorsal line, the other two are lateral and oblique. Dr. J. E. Gray regards the posterior plate as the homologue of the limpet shell.

The Chitons then resemble the other Mollusks: 1, in the general form of the body; 2, in the organ of locomotion; 3, in the nature, form, and position of the branchiæ; 4, in the heart, and in the distribution of the circulating vessels; 5, in the mouth and its veil; 6, in the tongue and the rest of the digestive organs; 7, in the position of the vent; and 8, last, but not least, in the nervous system.

What, then, are the differences? 1, the form of the shell composed of eight pieces instead of one; 2, the mantle, which is more fleshy and fibrous than in the other mollusks; 3, the myology; 4, the double issue of the organs of generation, allowing this difference to be established, whereas it is doubted. With regard to the absence of eyes, that defect exists in a considerable number of mollusks.

Professor E. Forbes and Mr. Hanley place the family *Chitonidæ* next before the *Patellidæ*. They say: "As our knowledge stands at present, we prefer to regard them as an abnormal family of *Prosobranchiata*, and trust before long that some active observer resident by the coast will occupy himself with studying the development of the Chitons, and endeavour to ascertain the form they assume in their larval condition. Whoever does so will make an important discovery, and do more towards fixing the true position of these anomalous creatures than all cabinet examinations of them have yet enabled us to effect."

Geographical Distribution.—The species are numerous, and there are few rocky shores without some of them. As a general rule, the largest are found in warm climates, but there are exceptions; for instance, *Chiton setiger* and *Chiton Bowenii* (King), are found on the shores of Tierra del Fuego, and in the Straits of Magalhaens; the former of these species grows to the length of 2⅜ inches, and the breadth of 1⅜ inches, and the latter to the length of 3¼ inches, and the breadth of 1½ inches.

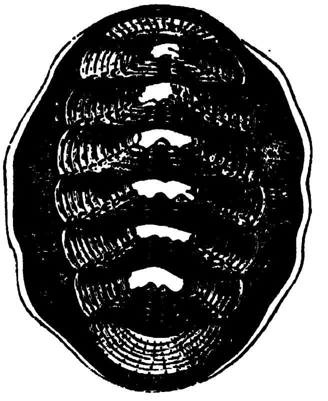
The species are found on rocky shores, where they adhere, and also on stones and other submarine bodies. They are found at depths varying from the surface to 25 fathoms. A few are found creeping on the sand.

Most zoologists are agreed that there are no differences sufficiently strongly marked to make a generic distinction between *Chiton* and *Chitonellus*; and, indeed, the gradations from the one to the other are so imperceptible, that there is no point where the line can be satisfactorily drawn. In the most completely-developed form of *Chiton* the shelly secretion greatly preponderates; in *Chitonellus* that secretion is comparatively small, and the great development is in the border of the mantle, which, in some instances, almost hides the comparatively-minute shelly pieces.

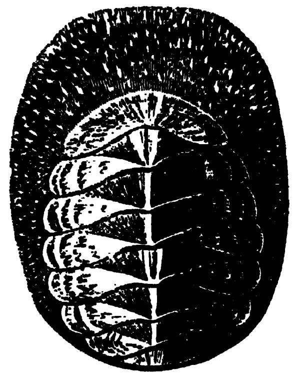
a. Species with the Mantle-Border, or marginal ligament, coriaceous and naked. Examples, *C. Chilensis*, Frembley, and *C. Blainvillii*, Broderip.

C. Chilensis. Shell oblong-ovate, opaque, thick, dark brown, smooth, dull; inside white, with pink markings on the first, second, and last valves. Valves with longitudinal striæ, crossed by irregular concentric ridges. Anterior and posterior valves semilunate, slightly punctated; second valve subcarinated, the front margin obtusely angled, lateral margins arcuate, and the posterior with a prominent beak, on each side of which diverges a rather elevated granulated ridge; the next five valves alike, bow-shaped, with a granulate ridge on each side. Border smooth, coriaceous, tough, thick, darker coloured than the shell, semipellucid, broad at the sides and narrow at the extremities. Locality, Valparaiso, in crevices of rocks and under stones. (Frembley.)

C. Blainvillii. In this species the shape of the coriaceous border itself is not only very remarkable, but it is here and there fringed, though not with hair. M. Deshayes has placed this under his section of those species which have the border of the mantle fringed with hair or spines, probably from not having seen a good specimen.



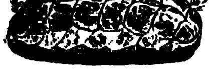
Chiton Chilensis.



Chiton Blainvillii.

β. Mantle-Border smooth, with tufts of hair at the lateral extremities of each plate.

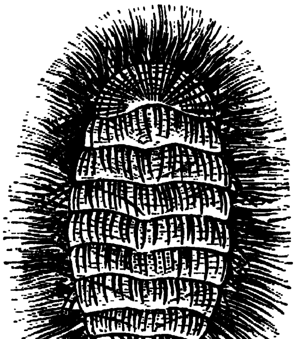
C. fascicularis, Linnæus. Shell, apparently smooth, but when examined with a glass, proving to be rough like shagreen, except on the elevated dorsal ridge; margin surrounded with tufts of whitish hair, one at the junction of each valve, and two in the front, making 18 in number. Colour brown or dark cinereous; length ⅝ths of an inch; breadth rather more than ¼th. Montagu, who gives this description, says, that on the coast of Barbary it is not unfrequently an inch long. It is found under stones at low water, and on stones and shells to a depth of 25 fathoms, all round the British shores. It ranges northward to the shores of Norway, and southward to the Mediterranean. Some remains of *Chiton* in the Crag have been referred by Mr. Searles Wood to *C. fascicularis.*



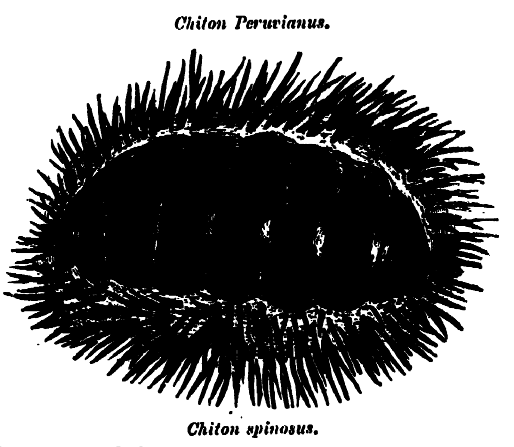
Chiton fascicularis.

γ. Mantle-Border hairy.

C. Peruvianus, Lamarck. Shell oblong-ovate, opaque, dirty-yellowish, green, or yellowish-brown, inside white. Valves thin, slightly elevated; posterior compartments of the dorsal valves a little raised and striated, with minute granulated striæ, and in like manner the other parts of the shell; under each valve is inserted a series of short black hairs, which lie on the back of the shell. Border narrow, coriaceous, thickly set with coarse black hairs. Length 2 inches, breadth 1¼ inch. Found under stones at low water on the shores of Valparaiso Bay. There is a variety with the anterior valves much narrower than the posterior. (Frembley.)



Chiton Peruvianus.

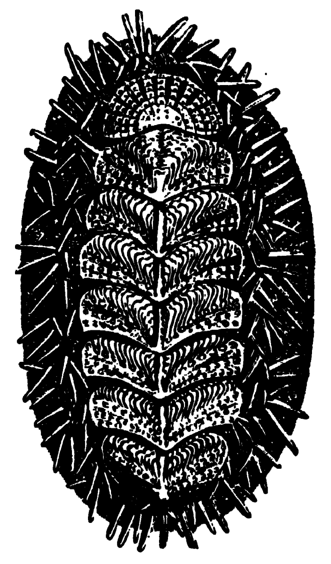


Chiton spinosus.

δ. Mantle-Border beset with spines.

C. spinosus. Shell brownish-black, valves opaque, moderate, with the sides granulated, the anterior valves entirely granulated. Mantle-border wide, and beset with long aculeated blackish spines, very much resembling those of certain *Echini.* Locality, South Seas, according to Péron. Length 3 inches.

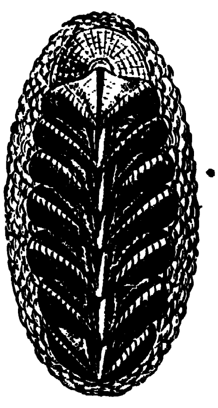
C. spiniferus (*C. aculeatus*, Barnes; *C. tuberculiferus*, Sowerby, in 'Tankerville Catalogue'). Shell opaque, oblong ovate, reddish-brown, glossy; inside reddish-white. The posterior angles of the valves do not cover the anterior ones. Anterior valve with generally nine rows of raised dots diverging from the apex, but the number perhaps varies with the age of the shell. Second valve rather acutely beaked and carinated, longer than the five following, which are striated and shaped alike; these all rise into a rather acute beak, are carinated, each side of the carina being divided into two distinct portions, the anterior one the largest, and bearing broad irregular longitudinal striæ; a prominent row of raised dots, extending from the apex to the anterior angles of the valves, separates the compartments; the posterior portion glossy, with fine concentric striæ; the posterior margins with tooth-like granulations. Last valve striated, like the anterior compartments of the others, and rising into a rather prominent beak, leaning towards the posterior margin; from under the beak are raised dots, disposed in a similar manner to those on the anterior valve. Border coriaceous, thick, broad, rough, greenish or orange-coloured, and in the younger specimens thickly studded with blunt spines; but in the old shells the spines are short and scanty, and generally covered with corallines; the inner edge of the border, inserting itself under the posterior angles of the valves, has the appearance of being deeply separated. (Frembley.) This species grows to the length of 5 or 6 inches, but has then generally lost all its external beauty. We have seen many individuals in all the stages of growth, and have invariably found the spines of the aged ones covered with that calcareous matter which is so frequently found adhering to shells and submarine bodies, but we have never detected anything organic about that which was attached to the spines of this species. Locality, Chili and Valparaiso, where Mr. Frembley found several specimens in very exposed situations; so much so, that collecting them was attended with much difficulty, and not unfrequently with danger, from the violence of the sea breaking on the rocks to which they attach themselves very strongly. They are generally covered with sea-weed.



Chiton spiniferus.

ε. Mantle-Border scaly.

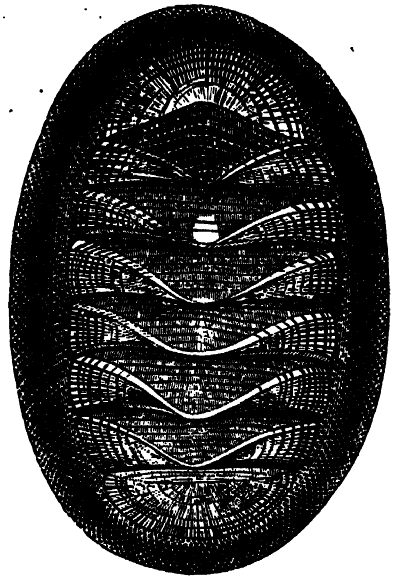
C. Coquimbensis, Frembley. Shell ovate, narrow, opaque, greenish-brown, shining; inside blackish: the anterior valves with numerous undulated, concentric ridges; the next rather acutely keeled; the five following alike: carina broad and smooth, on each side of which is a similar ridge diverging from the beaks, and forming with the carina a sagittate figure, and connected with it by several strongly marked ridges: from under the beaks to the anterior angles of the valves extend sharp moniliform ridges, each side of which is coarsely striated longitudinally. Border thick, moderately broad, and covered with coarse seed-like scales, which are attached laterally. Length 3 inches, breadth 1¼ inch. Mr. Frembley says, that the only part of the coast where he found this species was the south side of Coquimbo Bay: their habits, he adds, are very similar to those of *C. spiniferus*, with the exception that they seem more gregarious.



Chiton Coquimbensis.

ζ. Mantle-Border granulous.

C. magnificus, Deshayes (*C. olivaceus*, Frembley; *C. latus*, Sowerby). Shell opaque, ovate, olivaceous, dull, dotted with lighter coloured spots: inside glaucous. Anterior valve with regular radiating striæ, crossed by concentric ridges; posterior margin nearly straight. Dorsal valves obtusely beaked, divided laterally into two compartments, the anterior having regular longitudinal striæ, crossed with others very minute and concentric; from under the beaks diverge to the lateral margins of the valves coarse and more irregular striæ, which raise the posterior compartment above the other. The posterior valve has a well-defined apex, leaning towards the posterior margin. Border thin, moderately broad, and covered with fine shining bead-like granulations, of the same colour as the shells, divided into two distinct portions, the upper of which is composed of finer beads than the lower, and which are placed transversely. (Frembley.) The species grows to the length of 4 or 5 inches: we have seen one that reached 4½ inches when dead. There is another variety narrower than the ordinary individuals, and Mr. Frembley observes that, among the very young shells, some of them have their borders of a lighter colour than their shells, and spotted with black. Locality, Chili.

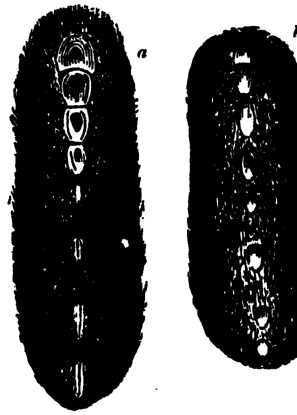


Chiton magnificus.

Species with the Mantle-Border highly developed, and the valves very small. (*Chitonellus*).

These are more or less cylindrical, and vermiform, the valves being very small, and in some species almost entirely hidden under the skin of the border, giving the animal an almost naked appearance.

Examples, *Chitonellus lævis*, and *C. larvæformis*.



a, Chitonellus lævis; b, Chitonellus larvæformis.

The following species are noted as British in Messrs. Forbes and Hanley's 'History of Mollusca':—*C. fascicularis*, *C. discrepans*, *C. Hanleyi*, *C. ruber*, *C. cinereus*, *C. albus*, *C. asellus*, *C. cancellatus*, *C. lævis*, *C. marmoreus*, and *C. punctatus*.

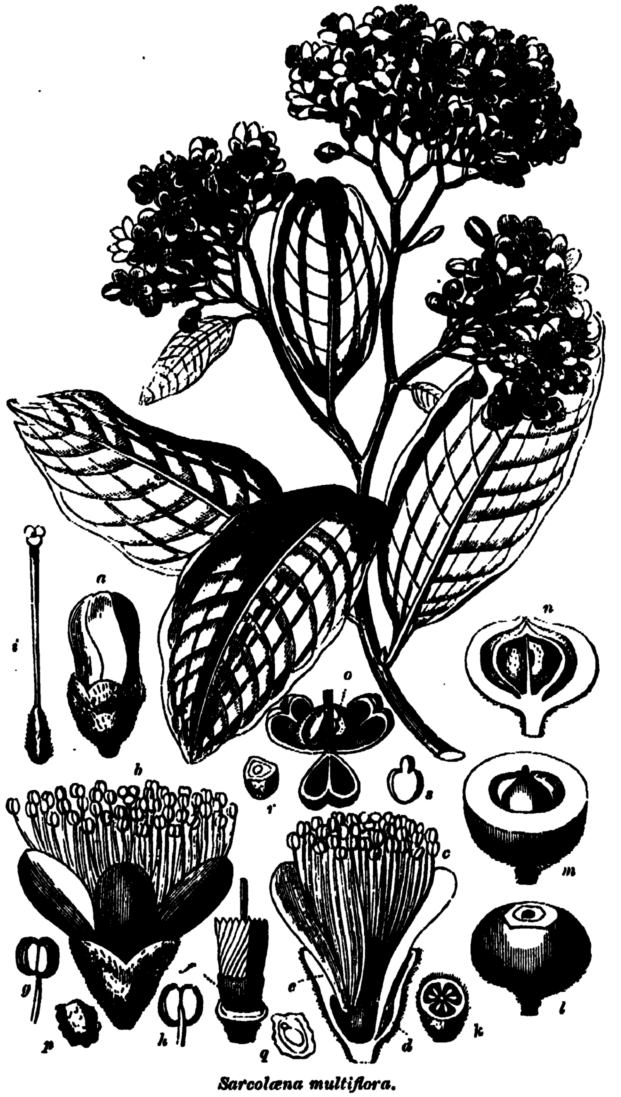
Above 200 species of this family have been described. The genus *Chiton* is divided by Dr. J. E. Gray and others into numerous sub-genera.

Fossil Chitonidæ.

Although from their fragility it might be supposed that few remains of these animals would be found, indications of their existence have been discovered as far back as the Palæozoic period. About 24 fossil species have been discovered. Three of these are given in Mr. Searles Wood's account of the Crag Mollusca, published by the Palæontographical Society.

CHIVES, the common name of *Allium schœnoprasum*. Its bulbs have the usual garlic odour of the genus, and are used in soups and stews: they are but little cultivated. [ALLIUM.]

CHLÆNA'CEÆ, *Chlenads*, a natural order of Polypetalous Exogenous Plants, by some accounted allies of *Malvaceæ*, but more correctly referred to the vicinity of *Cistaceæ*, from which, and all those associated with them in the Gynobasic Group, they differ in having an involucrum to each calyx, or to each pair of calices. They are handsome trees or shrubs, but of no known use. Their leaves are alternate and undivided, their stipules deciduous, and their flowers in panicles or racemes, always showy, and often red. There are four genera, *Sarcolæna*, *Leptolæna*, *Schizolæna*, *Rhodolæna*. The whole of the species, about eight in number, are wild in Madagascar.



Sarcolæna multiflora.

a, flower-bud; *b*, flower; *c*, vertical section of flower; *d*, the calyx; *e*, the involucrum; *f*, base of the flower, showing the spiral tube formed by the union of the filaments; *g*, *h*, back and front views of anthers; *i*, pistil; *k*, transverse section of ovary; *l*, fruit; *m*, transverse section of fruit; *n*, vertical section of fruit; *o*, pericarp, splitting and discharging its seed; *p*, seed; *q*, vertical section of seed; *r*, transverse section of seed; *s*, embryo.

CHLÆ'NIUS, a genus of Coleopterous Insects, of the family *Harpalidæ*, and section *Patellimanes* (Dejean).

The species of this genus are all of tolerably large size, very elegant in form, and generally adorned with various hues of green, the colours being rich, but not glossy, owing to the upper parts being more or less covered with a very delicate pubescence, which produces a silk-like appearance. Very many of the species have the legs and antennæ of a pale yellow colour, and the outer margin of the wing-cases of the same tint, and some have the elytra adorned with large yellow spots.

The genus *Chlænius* constitutes a very large group of the *Harpalidæ*, which, according to our views, embraces the genera *Epomis* and *Dinodes*. We will therefore briefly notice the distinguishing characters of these three groups.

All three of the genera agree in having the tarsi of the anterior pair of legs dilated in the males, and a bifid tooth in the middle of the emargination of the mentum; but they differ chiefly in the form of the terminal joint of the palpi, and the difference may be thus expressed:—

Terminal joint of the palpi.

Elongated and truncated at the apex,	*Chlænius.*
Elongated and distinctly securiform,	*Epomis.*
Short and slightly securiform,	*Dinodes.*

As regards the form of these insects, the body is generally more or less oval, and very slightly convex: the thorax is almost always considerably narrower than the elytra, broad towards the anterior part, and diminishing in width towards the posterior. The head is rather long, the eyes project considerably, and are rather remote from the base of the head; the portion of the head before the eyes is rather pointed.

The species are found under stones, weeds, and almost any rubbish which will afford them shelter; sometimes under the loose bark of old trees near the root, but they must be sought after in the vicinity of water.

Of the genus *Chlænius* M. Le Comte Dejean enumerates 115 species, a great portion of which are European; many are from Africa, the East Indies, and North America, but South America and Australia appear to be almost destitute of these insects.

Several species have been discovered in England. Of these however two only have been found in any abundance. *Chlænius vestitus* (*Carabus marginatus*, Linn.) is very common in the south of England, and is found under stones by the edges of ponds where gravel abounds. It is nearly half an inch in length, black beneath, and of a rich green colour above: the elytra are distinctly striated, very finely punctured, and covered with a delicate pubescence of a golden hue: their outer margin is of a pale yellow colour: this tint is confined to a narrow line towards the base of the elytra, but forms a broad patch at the apex; the head and thorax are rather glossy; the latter is finely punctured throughout, and has the margin slightly tinted with yellow; the legs, antennæ, and palpi are yellowish-white when the insect is alive.

Of the genus *Epomis* M. Dejean enumerates six species, one of which has been found in England. It is about three-quarters of an inch in length; the head and thorax are of an obscure brassy-green colour and slightly punctured; the elytra are black, with the outer margin pale yellow; the legs and antennæ are also yellow. This species is not uncommon in France and Italy.

The genus *Dinodes* only embraces four species. *D. rufipes* is about half an inch in length, of a rich blue colour above, and finely punctured throughout: the legs and base of the antennæ are of a reddish-yellow colour.

The thorax in this genus (taking *D. rufipes* as the type) is broader and more rounded than in the genera *Chlænius* and *Epomis*. The species described is found in France and Italy.

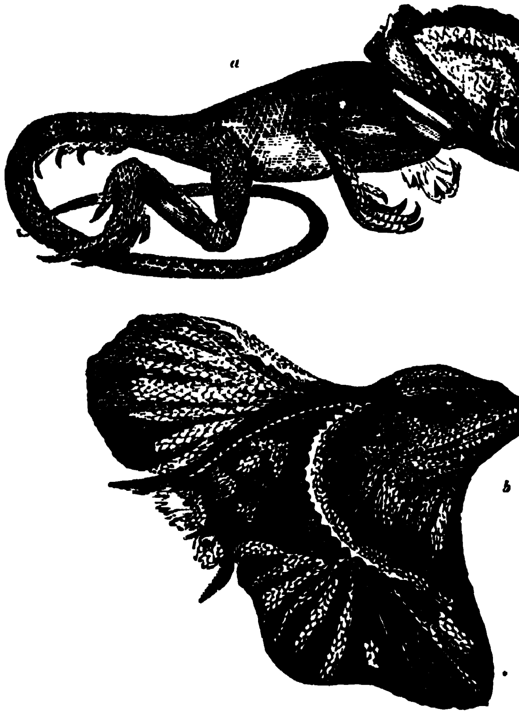
CHLAMYDOSAURUS, a genus of Saurian Reptiles, founded by Dr. J. E. Gray upon a specimen brought home by Captain Phillip Parker King, R.N., F.R.S., &c., on his return from his survey of the intertropical and western coasts of Australia, performed between the years 1818 and 1822. The following is Dr. Gray's description:—

Animal scaly; the head depressed; the nostrils placed on the side, midway between the eyes and the end of the head; the drum of the ear naked; the front teeth conical, awl-shaped (eight in the upper and four in the lower jaw), the hinder ones longest; the side or cheek teeth compressed, short, forming a single ridge, gradually longer behind; tongue short, fleshy, with an oval smooth disc at each side of the lower part of its front part; neck rather long, furnished on each side with a large plaited frill, supported above by a crescent-shaped cartilage, arising from the upper hinder part of the ear, and in the middle by an elongation of the side fork of the bone of the tongue; body compressed; legs rather long, especially the hinder ones; destitute of femoral pores; feet four, with five toes, the first having two, the second three, the third four, the fourth five, and the little finger and toe three joints; claws compressed, hooked; tail long, nearly round, scaly.

Chlamydosaurus Kingii. Colour yellowish-brown, variegated with black. Head depressed, with the sides erect, leaving a blunt ridge on the upper part wherein the eyes are placed. The ridge over the eyes is covered with larger scales than those over the head. The eyes are rather small, with a fleshy ridge above them, and the eyelids are covered with minute scales, and surrounded by a delicate serrated ridge of small upright ones. The lips are surrounded by a row of oblong 4-sided scales, arranged lengthways, the front scale of the upper lip being the largest. The chin is covered with narrow mid-ribbed scales, with a 5-sided one in the centre, and several of larger size just over the front of the fork of the lower jaw. The nostrils are surrounded by a rather large orbicular scale, situated nearly midway between the eye and the end of the upper-jaw, the tubes pointing forwards. The side of the face has a very obscure ridge extending from the angle of the mouth to the under part of the ear. The neck is covered with small scales. The frill arises from the hinder part of the head, just over the front of the ears, is attached to the sides of the neck, and extends down to the front part of the chest, supported above by a lunate cartilage arising from the hinder dorsal part of the ear, and in the centre by a bone which extends about half its length. Each frill has four plaits which converge on the under part of the chin, and fold it up on the side, and a fifth where the two are united in the centre of the lower part of the neck. The front part of its upper edge is elegantly serrated, but the hinder or lower part is quite entire: the outer surface is covered with carinated scales, those in the centre being the largest. The inner surface is quite smooth. The scales of the back are oval, and nearly smooth; those of the lower part of the body and upper part of the legs have a short mid-rib, and those of the sides and joints of the limbs are minute. The tail is twice as long as the body, roundish, covered with scales which have each a sharp mid-rib, and towards the termination, which is blunt, form six rows, so as to render that organ obscurely hexagonal. The toes are long, very unequal, compressed, and scaly. The claws are hooked, and horn-coloured.

Dimensions.—Length of the tail 12 inches; of the body 5 inches; of the head 5½ inches. Breadth of the head over the eyes one inch. Length of the thigh 1$\frac{8}{10}$ inch; of the foot and sole 2⅓ inches; of the outer edge of the frill 10 inches.

Locality and Habits.—We owe the discovery of this extraordinary Saurian to Mr. Allan Cunningham, who accompanied Captain King's expedition as his Majesty's botanical collector for Kew Gardens, and to whom naturalists in general are so much indebted for the zeal displayed by him in the pursuit of natural history, and for the liberality with which he has communicated the results of his labours. He found the specimen from which the description was taken on the branch of a tree in Careening Bay, at the bottom of Port Nelson, and sent it to Sir Everard Home, by whom it was deposited in the Museum of the Royal College of Surgeons. The following is the account of the capture in Mr. Cunningham's Journal:—"I secured a lizard of extraordinary appearance, which had perched itself upon the stem of a small decayed tree; it had a curious crenated membrane, like a ruff or tippet round its neck, covering its shoulders, and when expanded, which it was enabled to do by means of transverse slender cartilages, it spreads 5 inches in the form of an open umbrella. I regret that my eagerness to secure so interesting an animal did not admit of sufficient time to allow the lizard by its alarm or irritability to show how far it depended upon, or what use it made of, this extraordinary membrane when its life was threatened. Its head was rather large, and eyes, whilst living, rather prominent; its tongue, although bifid, was short and thick, and appeared to be tubular." According to Captain King, the colour of the tongue and inside of the mouth was yellow. Dr. J. E. Gray arranges this genus under the family *Agamidæ*. [AGAMA.]

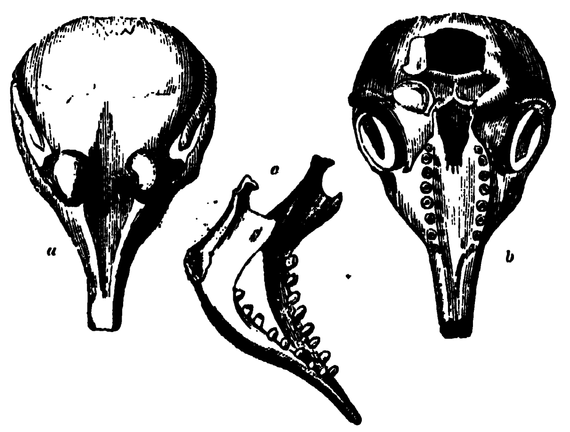


Chlamydosaurus Kingii.

a, the animal in the Museum of the College of Surgeons; *b*, representation of the living head, from the 'Appendix' to Captain King's 'Voyage.'

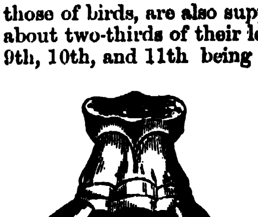
CHLAMY'PHORUS (Harlan), a genus of *Mammalia* belonging to the order *Edentata*. It was first described by Dr. Harlan in the 'Annals of the New York Lyceum of Natural History,' vol. i., from a specimen presented to the Philadelphia Museum. It is the Pichiciago of the Indians in Mendoza (its native place), on the east of the Cordilleras, in lat. 33° 25′, and long. 69° 47′. It had been obtained on the spot in a living state, but lived in confinement only a few days. The viscera and the greater portion of the skeleton had been removed before the animal came into Dr. Harlan's possession. In March 1828 the council of the Zoological Society of London placed in the hands of Mr. Yarrell a specimen of this rare and new animal, and to his dissection we are chiefly indebted for our knowledge of its structure. The following account is an abstract of Mr. Yarrell's paper in the 'Zoological Journal.'

The form of the head presents the figure of an irregular cone, the base of which is turned towards the spine; the cranium does not exhibit any sutures; the cavity capacious; the frontal bone supporting two rounded processes projecting upwards and somewhat outwards; the space between them occupied by a substance resembling in appearance adipose matter, from which issued a fluid like oil. From the anterior part of the base of these two rounded processes, a narrow ridge of bone extends forwards on each side converging towards the nose. The nasal bones elongated, the orifice opening downwards. No incisor nor canine teeth in either jaw; molars $\frac{8}{8}$, cylindrical, separate, encircled with enamel, but none on the crowns: the first tooth on each side in the lower jaw, having no opponent, is the longest, the remaining seven opposed to the first seven of the upper jaw, and taking angular impressions on their surfaces by contact; the direction and depth of the alveolar cavities of the upper jaw distinctly marked on the outside by parallel ridges; in the lower jaw the alveolar cavities are pierced the whole depth. The anterior portion of the lower jaw is elongated; the inferior edge concave the first half of its length, then convex; the plate broad, rising at right angles with the line of the teeth; the condyloid process longer than the coronoid, the condyle itself elongated transversely. The external meatus auditorius is extended in the form of a semicircular cylindrical tube of bone, curving round the base of the zygoma, and passing forwards terminates in an aperture immediately behind the eye. The orbits and temporal fossæ united; the zygomatic arch is slender posteriorly, but becomes much stronger towards the front, expanding downwards, and furnished with an acute descending process. The occipital foramen is of great size.



Skull of *Chlamyphorus truncatus*.
a, Skull seen from above; *b*, the same seen from below; *c*, lower jaw.

The cervical vertebræ 7, the first large, the articulating surface broad; the 2nd, 3rd, and 4th very firmly ossified together, pierced with foramina for the passage of the cervical vessels; the 5th united to the 4th on the under surface only; the 6th and 7th slender and separate, allowing the head great freedom of motion upwards; the whole of the last six grooved on the under surface, in the line of the passage of the œsophagus. Dorsal vertebræ 11, the spinous process of the first slender, three-eighths of an inch long, the others diminish gradually in length, but increase in size; all directed backwards. The first rib is very broad, and from the 2nd to the 8th the ribs of the *Chlamyphorus*, like those of birds, are firmly united to the sternum without the intervention of an elongated cartilage; and, again like those of birds, are also supplied with a false joint, at the distance of about two-thirds of their length from the spine to the sternum. The 9th, 10th, and 11th being false ribs are united in the usual way to each other, and to the 8th by elongations of cartilage from their extremities. The portions of ribs intervening between the false joints and the sternum are in the 6th, 7th, and 8th ribs, consolidated, broad, flattened portions of bone, which form the boundary of the anterior and lateral parietes of the thorax. The first bone of the sternum is broad and flat, the superior surface regularly concave, the inferior irregularly convex. Upon the anterior edge of the sternum are two prominences to which are attached the extremities of each clavicle. From each of these articulations a slightly elevated ridge proceeds backwards along the inferior surface of the sternum, converging towards the centre, where they become united, and form a prominent crest. The lateral edges of this first bone of the sternum are articulated at its anterior extremity to the first and broadest rib; from this part the bone suddenly becomes narrowed posteriorly, and terminates in a concave articular surface to which the second bone of the sternum is attached. Judging from the imperfect remains of the second bone, of which the upper part only was distinguishable, it would appear that its form was oblong, the superior surface concave. The remaining portion of the sternum was too much mutilated to admit further description.



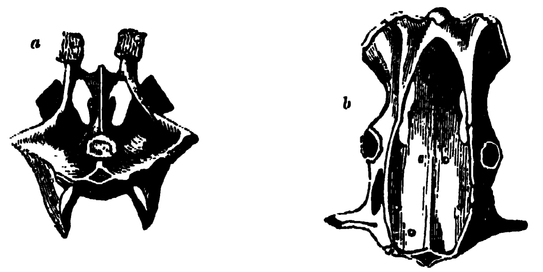
Cervical Vertebræ, first bone of the sternum, with parts of the first and second ribs, seen from below.

Lumbar vertebræ 3, the spinous processes short and flattened; the last two dorsal vertebræ, as well as the lumbar, furnished with long oblique processes directed forwards, upwards, and outwards; the transverse processes of the first two lumbar vertebræ considerably elongated, the last possessing a rudiment only.

The whole of the sacrum and innominata is so peculiar and unique in character, that it is scarcely possible to give any correct idea of this part without the assistance of accurate representations. The superior part of the ilium is flattened, the upper part bent to form an arched plane of bone, the concavity of which faces downwards and outwards; the crista of great length from before backwards. The inferior portion of the ilium is much stronger, inclining outwards, from its junction with the sacrum to the acetabulum.

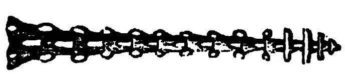
The transverse and spinous processes of the sacrum are represented by three slender plates of bone, which, approximating as they pass backwards, are united to form a septum, extending down the median line of the sacrum to the tail. A channel is formed on each side of this septum by a thin flat plate of bone, which, arising from the posterior and superior part of the ischium on each side, is bent over the back part of the sacrum and fixed to an arched and prominent plate of bone, which is extended from this septum outwards to form a junction with it. The channels thus produced are bounded below by the sacrum, on the inner sides by the septum, on the outer sides by the ascending plates of bone just described, and above by the junction of both. From this union a short osseous stem issues horizontally on each side, and expands into a flattened circular plate of bone, to the rough surface of which, as well as to the tuberosity of the ischium below, portions of the truncated exterior of the animal are firmly attached.

The under surface of the sacrum is broad and flattened, and marked by an indistinct central ridge. The pelvis is open in front, the ossa pubis on each side do not incline inwards, but descend at right angles from the horizontal surface of the sacrum. In the circumstance of the pelvis being open there is a second resemblance to the bony structure in birds.



a, the Pelvis seen from behind; *b*, the same seen from below.

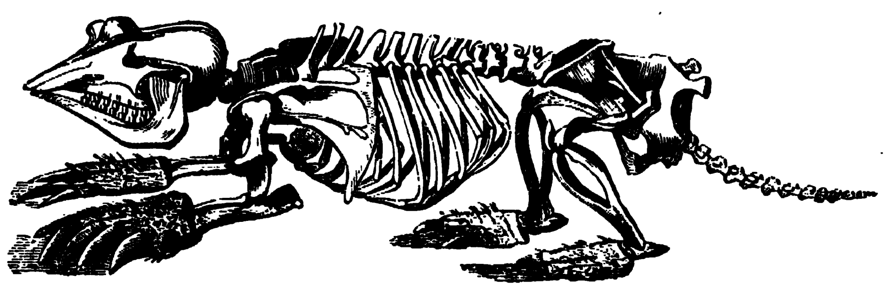
The caudal vertebræ are 14 in number; the transverse processes of the last four are elongated, to support the thin dilated lateral edges of the paddle or spatular extremity of the tail. Large muscles are imbedded in the two cavities formed on the upper surface of the sacrum by its septum and the two lateral elevated portions of the ischium before described; and there are antagonist muscles of equal size on the under surface. The tendons of these muscles were inserted on the upper and under parts of the caudal vertebræ, giving great power to the tail, which is probably exercised in removing backwards the loose earth accumulated under the belly of this burrowing animal by the action of the fore legs, and for which purpose the expanded and flattened extremity seems well calculated.



Vertebræ of the tail.

The scapula has its superior margin straight, ending in a notch of great size; the base rounded; the inferior margin concave, and the posterior inferior angle considerably elongated; the coracoid process but little produced, the spine elevated, the acromion very long, passing forwards, downwards, and inwards, over the head of the humerus, to be articulated to a long and slender but perfect clavicle. There is a second spine of smaller size, parallel to but beneath the true spine. The humerus is three-fourths of an inch in length, large, and broad; the deltoid crest prominent; between which and the external condyle a deep groove is formed for the lodgment of muscles, &c.; both condyles very much elongated transversely; the inner condyle perforated above; the edge rising from the external condyle acute. The radius small, and seven-sixteenths of an inch in length; the ulna flattened, concave upwards, the olecranon nearly as long as the ulna, horizontally flattened also, and presenting a superior concave surface, ending in a curve pointing downwards. The feet furnished with sesamoid bones for the insertion of the tendons of the flexor muscles.

The femur, thirteen-sixteenths of an inch long, large and strong; the length of the neck considerable; the great trochanter elongated backwards beyond the line of the articulation of the head of the femur with the acetabulum, and ending in a tuberosity; the lesser trochanter directed downwards; a trochanter projecting from the outer side of the shaft of the femur somewhat above the middle; the condyles moderately elongated transversely, the outer having a crest directed backwards. The tibia and fibula fifteen-sixteenths of an inch, flattened, concave inwards, firmly anchylosed at each extremity, and arched in opposite directions, giving an appearance of great size and strength to the leg. The os calcis elongated backwards, flat, and ending in a curve slightly inclined upwards. Hind feet plantigrade.



Skeleton of *Chlamyphorus truncatus*, with the exception of the feet, which are covered with the integuments.

Mr. Yarrell observed the following points of resemblance between the skeleton of *Chlamyphorus* and that of other *Mammalia*:—1. Beaver (*Castor Fiber*), in the form and substance of some of the bones of the limbs, in the flattened and dilated extremity of the tail, and the elongation of the transverse processes of the lower caudal vertebræ, but no further. 2. Mole (*Talpa Europæa*), in the shortness and great strength of the legs, and in the articulation of the claws to the first phalanges of the toes; but in the form of the bones of the anterior extremity, as well as in the compressed claws, it is perfectly different, nor do the articulations of the bones, nor the arrangement of the muscles, allow any of the lateral motion so conspicuous in the mole. The hinder extremities of *Chlamyphorus* are also much more powerful. 3. Sloth (*Bradypus tridactylus*), in the form of the teeth, and in the acute descending process of the zygoma, but not otherwise. 4. Armadilloes (*Dasypi*), in the coat of mail, in the peculiar ossification of the cervical vertebræ, in possessing the sesamoid bones of the feet, and in the general form of the bones, except those of the pelvis; they differ however in the form and appendages of the head and in the tail. 5. *Orycteropus Capensis* and *Myrmecophaga jubata*, in some of the bones. 6. *Echidna* and *Ornithorhynchus*, in the form of the first bone of the sternum, and in the bony articulations as well as the dilated connecting plates of the true and false ribs. 7 and 8. *Ruminantia* and *Pachydermata*, in the form of the lower jaw, and in other points equally obvious. The unique points in its structure appear to be the form of the head and the open pelvis.

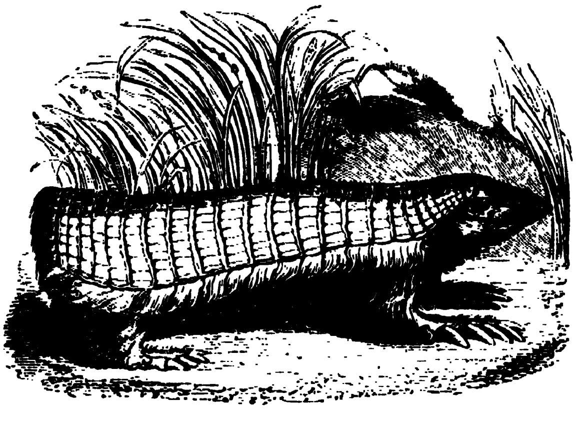
According to Dr. Harlan, the total length of the entire animal is 5¼ inches. The shell which covers the body is of a consistence somewhat more dense and inflexible than sole-leather of equal thickness, and is composed of a series of plates of a square, rhomboidal, or cubical form, each row separated by an epidermal or membranous production, which is reflected above and beneath, over the plates: the rows include from 15 to 22 plates, the shell being broadest at its posterior half, extending about one-half round the body. This covering is loose throughout, excepting along the spine of the back and top of the head, being attached to the back immediately above the spine by a loose cuticular production, and by the two remarkable bony processes on the top of the os frontis, by means of two large plates, which are nearly incorporated with the bone beneath; but for this attachment the covering would be very easily detached. The number of rows of plates on the back, counting from the vertex, where they commence, is 24; at the twenty-fourth the shell curves suddenly downwards, so as to form a right angle with the body; this truncated surface is composed of plates, nearly similar to those of the back; they are disposed in semicircular rows, five in number; the lower margin, somewhat elliptical, presents a notch in its centre, in which is attached the free portion of tail, which makes an abrupt curvature, and runs beneath the belly parallel to the axis of the body, the extremity of the tail being depressed, so as to form a paddle; the rest of the tail compressed. The superior semicircular margin of the truncated surface, together with the lateral margins of the shell, are beautifully fringed with silky hair.

The posterior half of the head broad, anterior half, before the eyes, tapering; the occiput is covered by the first five rows of the back plates with which they are continuous; the occiput not distinguishable externally. The anterior half of the top of the head is covered, first, by a row of large plates, five in number, which are firmly attached to the bone beneath, particularly the two outer; secondly, by a smaller row, six in number, anterior to which, that is to say, the top of the snout, is covered with smaller plates irregularly disposed.

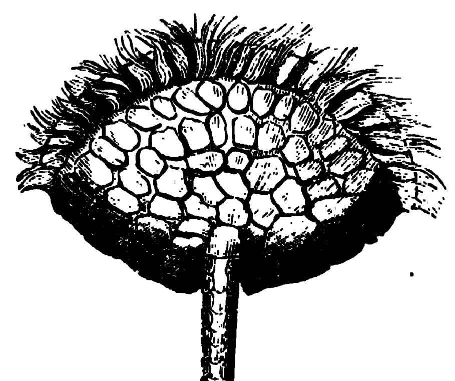
Mr. Yarrell observes that when separating the skin from the muscles of the back the fibres (described by Dr. Harlan) by which the outer coat was attached in the line of the vertebræ were found to be adherent to the muscles immediately investing the spinous processes, and each of them, Mr. Yarrell supposes, probably affords a nidus for vessels nourishing the external covering; but these attachments did not extend below the dorsal vertebræ. Proceeding from thence forwards the great size of the muscles of the scapulæ and neck was apparent, filling up the whole space, the back and upper portion of the head forming one continued line. The thick plate of scales covering the frontal portion of the head was without difficulty separated from the surfaces of the singular bony processes of the os frontis; the projecting cartilaginous portion of the nose was removed with the skin, and the tendons of several muscles giving motion to the snout were cut through.

The hinder portion of the body still remained to be separated from the skin, and this was found to be a matter of some difficulty. The posterior and inferior portions of the sacrum on each side were firmly united by distinct attachments, differing in form, to certain scales of the truncated extremity of the outer covering.

The necessity of preserving this outer covering entire rendered a division of these portions of bone necessary, and from the particular form of the part this was attended with some hazard, but was ultimately accomplished without injury, the bones being cut through as near to and as parallel with the inner surface of the plates as their confined situation would admit. The covering of the tail was separated from the vertebræ as far as the flattened extremity, where the greater elongation of the transverse processes of the last four vertebræ and the tenuity of this flattened portion made further separation



Chlamyphorus truncatus.



Truncated extremity and tail.

difficult. The tail was then divided between the tenth and eleventh vertebræ, and both parts of the animal entirely separated.

On the inner surface of the removed skin were two long broad and thin muscles extending the whole length of the back; each muscle was divided as it approached the shoulder into two portions; the outer one was attached to the superior and greater spine of the scapular bone; the inner and longer slip proceeded forwards, and was inserted into the transverse occipital ridge. The posterior extremity of each muscle was attached to the superior edge of the spine of the ilium. The external ear, according to Dr. Harlan, consists of a circular somewhat patulous opening, directly posterior to the eye, surrounded with an elevated margin, and communicating with a bony canal. The eye is minute, totally black, and, like the ear, nearly hidden by long silky hair. The mouth is small. The nose is furnished with an enlarged cartilage, as in the hog, the anterior nares opening downwards at the inferior border.

The whole surface of the body is, it appears from the same author,—and the correctness of his description is proved by an inspection of the stuffed specimen—covered with fine silk-like hair, longer and finer than that of the mole, but not so thick set. The anterior of the chest is large, full, and strong; the anterior extremities short, clumsy, and powerful; the hair is continued for some distance on the palm—the phalanges of the hand united; five powerful nails rising gradually one above the other, the external shortest and broadest; the whole so arranged as to form a sharp cutting instrument, rather scooped, very convenient for progression under ground, and such as must very much impede motion on the surface. Hind legs weak and short; feet long and narrow; the sole resembles considerably the human foot, having a well-defined heel, which rests flat upon the ground, and being arched in the middle; toes separate, nails strong.

In the specimen dissected by Mr. Yarrell the abdomen and thorax had been opened throughout their whole length, and the viscera from both cavities had been entirely removed. Adhering to the skin lining the truncated portion of the animal were two sacs, which had been lodged in cavities on each outer side of the sacrum, immediately under the superior projection, made evident by the corresponding depression in the investing muscle of that part. These globular bags were lined with a secreting surface, but having suffered some mutilation in removal, the mode by which the secretion passed, or its particular use, could not be ascertained. Mr. Yarrell thinks that they are probably analogous to the well-known anal glands of various other quadrupeds.

According to Mr. Closeberry, who first discovered this animal, the habits of *Chlamyphorus* resemble those of the mole, as it lives for the most part under ground. He adds that the animal is reputed to carry its young beneath the scaly cloak with which it is covered, and that the tail possesses little or no motion.

CHLAMYS. [CHRYSOMELIDÆ.]

CHLENACEÆ. [CHLÆNACEÆ.]

CHLORA, a genus of plants belonging to the natural order *Gentianaceæ.* It has 8 sepals, a rotate corolla with 6-8 segments withering round the capsule, the stigma bi-lamellate, the anthers not altering, the capsule 1-celled with spongy placentæ, the seeds angular.

C. perfoliata, Yellow-Wort, has the lowermost leaves elliptico-oblong, narrowed below; the leaves of the stem broadly perfoliate. The corollas are of a bright-yellow colour, and the stigmas are scarlet. The whole plant is glaucous, and is very subject to attacks of mildew. It is a native of chalky hills and banks in most countries of Europe. It is found in England and Ireland, but not in Scotland. Like the whole order to which it belongs it possesses a bitter principle, which renders its action on the system tonic. It may be used in all those cases of debility and in diseases where the roots of the *Gentiana* and *Erythræa* are recommended. Its tonic properties are not however so powerful as in many other species of the order.

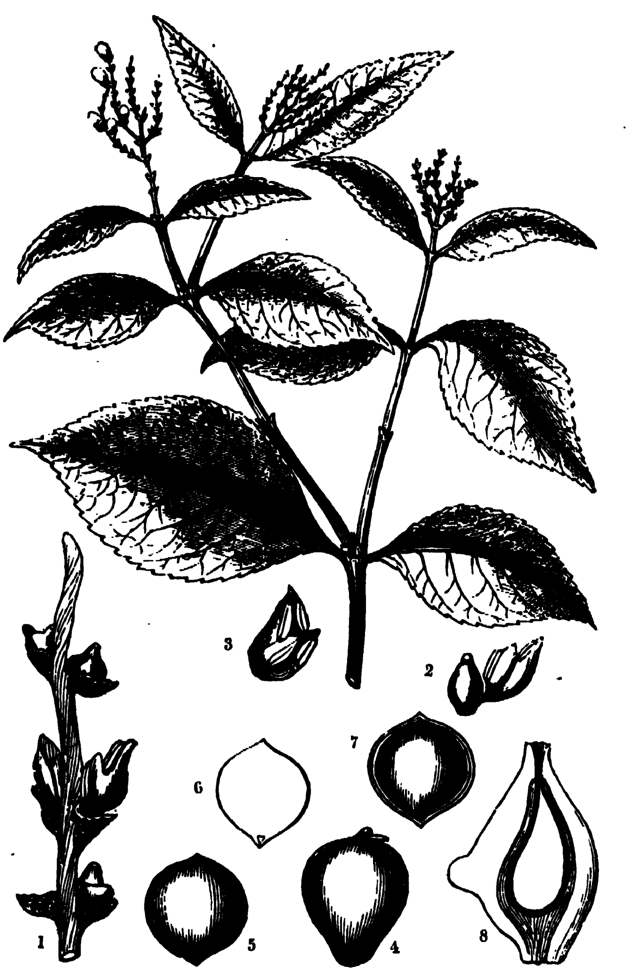
(Lindley, *Flora Medica;* Babington, *Manual of British Botany.*)

CHLORANTHA'CEÆ, *Chloranths,* a natural order of Achlamydeous Exogenous Plants allied to the Peppers, and like them having an aromatic fragrant odour. They are known from the orders associated with them by their jointed stems and opposite leaves, with intermediate stipules. Their flowers grow in naked spikes, and consist of an ovary next the axis of inflorescence, and a fleshy anther on the outside. Besides *Chloranthus* [CHLORANTHUS] two other genera, *Hedyosmum* and *Ascarina,* constitute this order. In structure they are allied to *Piperaceæ, Urticaceæ,* and *Saururaceæ.* The order contains about 15 species.

CHLORANTHUS, a genus of plants belonging to the natural order *Chloranthaceæ.* It has spiked flowers, each with a bract. Calyx absent. Anther solitary and 2-celled, or triple and 4-celled, with a thick fleshy connective; seated on the exterior side of the ovary. The stigma sessile. Drupe baccate, 1-seeded.

C. officinalis is a smooth shrub 3-4 feet high, with opposite straggling branches, tumid at the articulations, fistular when young. Leaves spreading, opposite, stalked, oblong, acuminated at each end, with glandular serratures, thin, shining, and somewhat blistered; petioles short and taper. Spikes terminal, branched. Bracts dotted with glands. Anther white, changing to yellow. Drupe straw-coloured. All the parts are powerfully aromatic; the roots, if quickly dried, retain their properties for a long time. The plant is a native of Java, in the moist woods, at an elevation of 1500 feet above the level of the sea.

The mountaineers of Java employ the roots in infusion as a remedy for spasms; also when united with Anise or *Ocymum* it is given in small-pox. In fevers and a suppression of the functions of the skin it is said to be of the greatest service. It is no doubt a powerful and active stimulant.



Chloranthus officinalis.

1, Spike, the upper and lower flowers without stamens; 2, flower without its bract; 3, an interior view of the anther; 4, a magnified fruit; 5, the kernel of the fruit; 6, a section of the fruit, showing the embryo; 7, the stone of the fruit, with a portion of the shell removed; 8, a perpendicular section of the ovary, showing the position of the ovule.

C. brachystachys is also a native of the coast of Java. It is an upright bush about 3 feet high, quite smooth in all its parts. Leaves obovate, lanceolate, tapering very much into the petiole, sharply serrate. Spikes short, terminal, branched. Bracts glandular. Anther simple, 2-celled, growing from the side of the ovary. Its properties are like those of the last species.

CHLO'RION, a genus of Hymenopterous Insects of the section *Fossores.* [SPHEGIDÆ.]

CHLORITE, a Mineral of a dark olive-green colour belonging to the talc, or hydrous silicate of magnesia series. It occurs in masses of a granular texture, rarely in hexagonal crystals, foliated like talc. It has a slight pearly lustre, and is sub-translucent or opaque, rarely sub-transparent. Its hardness is 1·5; specific gravity, 2·65 to 2·85. It has the following composition:—

Silica	30·4
Alumina	17
Magnesia	34
Protoxide of Iron	4·4
Water	12·6

It fuses with difficulty on the thinnest edges. Its olive-green colour and granular structure distinguish it from Serpentine. It may be known from Talc by its yielding water on fusion.

Chlorite Slate is an impure variety which occurs abundantly, sometimes in slaty rocks.

CHLORITOID, a Mineral of a greenish-black colour, and coarsely foliated. It is one of the hydrous silicates of alumina. No analysis of it appears to exist. It comes from the Ural Mountains, and has a hardness = 5·5, and a specific gravity = 3·55. (Dana, *Mineralogy.*)

CHLOROMYS. [AGOUTI.]

CHLOROPAL is a Mineral of a greenish-yellow or pistachio-green colour. It is a Silicate of Iron.

CHLOROPHÆITE, a Mineral found by Dr. Macculloch in the Isle of Rum. It occurs in small masses imbedded in basalt or a black indurated ironstone. Its colour when fresh broken is green, which becomes black by exposure to the air. It is brittle and soft enough to be scratched with a quill. Its specific gravity is 2·02. Some specimens are transparent, others are opaque. The lustre is vitreous; the fracture of the transparent sort is conchoidal, of the opaque intermediate as to conchoidal and granular. (Phillips's *Mineralogy*.)

CHLOROPHANE. [FLUOR.]

CHLOROPHYLE. (*Endochrome, Phytochlore, Chromule.*) The green colouring-matter of plants. It is obtained by bruising, pressing, and then washing leaves with water, and afterwards treating them with alcohol, which dissolves the green colour and wax; when water is added to this solution, and the alcohol distilled, the green substance, which contains wax, floats on the surface of the water; when this is heated with ether, the wax is dissolved, and Chlorophyle remains nearly pure. When exposed to light, or the action of chlorine, it is bleached. Acids produce a similar effect, and by the alkalis it is converted into soap. The red tint which leaves assume in autumn appears to be owing to the formation and action of an acid; the green colour is restored by an alkali.

This substance has been recently investigated with great care by Mulder, and the following account of it is chiefly derived from his researches as given in his 'Chemistry of Animal and Vegetable Physiology.':—

It is a striking fact that young leaves have a much lighter green colour than those which are older, showing that the quantity of Chlorophyle increases with the age of the leaves. If Chlorophyle were a substance poor in oxygen, and were derived from substances rich in oxygen, this fact alone would be sufficient to explain the power which the green parts possess of separating oxygen. This however is not the case: Chlorophyle is rich in oxygen. Nevertheless the leaves give off oxygen not because they are green, but whilst they are becoming green.

When green leaves are digested with ether the liquid becomes green. On evaporating the etherial solution, and treating the residue with hot alcohol, a considerable amount of white fatty matter (wax) separates on cooling, while the green colouring-matter remains in solution. Before proceeding to the consideration of the green colouring-matter, it will be expedient to say a few words respecting the mixture it forms with the wax.

In a physiological or botanical sense this mixture has the name of Chlorophyle; in a chemical sense the term is restricted to the actual green pigment. To prevent confusion, the former is designated as B. Chlorophyle, and the latter as C. Chlorophyle; B. indicating the botanical, and C. the chemical signification of the word.

We find similar mixtures of a waxy fat and colouring-matter in other external parts besides the leaves, namely, in the skins of fruits, especially of such as are coloured; and on digesting them in ether we obtain a large quantity of waxy matter in solution, varying in tint according to the colour of the skin; being gray when obtained from apples, and of a beautiful orange-colour when obtained from the berries of the Mountain-Ash.

The degree in which the action of light contributes to the change of colour in the C. Chlorophyle which exists in the perisperms, and to the production from it of the colouring-matter of the skin of ripe fruits, may be obviously inferred from the green colour which such fruits retain if they do not receive a sufficient supply of solar light, or from the difference of colour exhibited by the opposite side of the same fruit, as well as from the fact that leaves when deprived of the action of light become colourless, while if completely exposed to its action they secrete a considerable amount of B. Chlorophyle.

This apparently anomalous difference in the action of light on the skins of fruits and on leaves is dependent on the same cause as the change of colour in the leaves during autumn; namely, that light can only produce B. Chlorophyle when there is a sufficient supply of materials for its renewed formation as often as the existing quantity is decomposed by the influence of the light; and that as soon as this supply is exhausted the green colouring-matter is itself decomposed, and other compounds are formed from it.

Light acts powerfully in keeping plants green, and likewise exerts a powerful decomposing action upon all colouring-matters, the C. Chlorophyle not excepted; thus asparagus, potatoes, young leaves, &c., become green whenever they are exposed to light, and hence there must be a substance widely diffused through plants, which causes the production of Chlorophyle. The change takes place not merely on the surface, but beneath it as far as light can penetrate through the semi-transparent parts. All plants however are not coloured green; some have no colour at all, while others are speckled or spotted, or of a colour entirely different from green. Hence we conclude that in these plants or parts of plants, the materials yielding Chlorophyle are absent. We may sometimes observe in summer one single spot of a green leaf coloured red by the action of insects or by being injured by hail; the green colouring-matter is at the spot decomposed by the light; no new portion is formed, and the spot acquires the same colour which the whole leaf would have assumed in autumn. From this we infer that the change of colour in the leaves during autumn is simply dependent on a chemical alteration of the green colouring-matter by light.

Mulder, after showing from a large number of facts that wax along with a green colouring-matter exists in leaves and unripe fruits,—wax, with a red colouring-matter, in the red leaves which appear in autumn, and in the red fruits,—and wax with a yellow colouring-matter, in the yellow leaves of autumn, and in the yellow fruits—gives a lengthened chemical description of Chlorophyle, for an account of which we must refer to the original work.

From Mulder's experiments, and those previously instituted by Berzelius, it appears that the green colouring-matter of the leaves is readily decomposed into three different substances, one yellow, another blue, and a third black; and that according to the proportion of these three mixed with the green, a different kind of green must be produced. Hence the difference in the green colour of different leaves depends not only on the presence of more or less Chlorophyle, but also on the different mutual proportions of these three colouring-matters.

The quantity of pure C. Chlorophyle contained in the leaves is exceedingly small; according to Berzelius it is not more than the amount of pigment in dyed cotton.

If a tincture of pure Chlorophyle be exposed to the action of the sun the green colour becomes in a few hours converted into a yellow. When a solution of pure Chlorophyle in ether and hydrochloric acid was kept for five months in a bottle half full, the green was entirely changed into a yellow. From these experiments we learn, first, that the green colouring-matter is decomposed and a yellow one left, both with and independently of the influence of light; and secondly, that in all probability a similar decomposition (accompanied by a reproduction) of green colouring-matter and green leaves is constantly going on under the influence of light. Mulder conceives that the continual decomposition of the green colouring-matter may be in part the origin of the wax, since the quantity of the latter is found to have increased when the same leaves are analysed later in summer. In consequence of the continuance of this reproduction, the leaves remain green; when it stops, the leaves become yellow as in autumn.

It is worthy of notice that decomposed Chlorophyle yields a blue colouring-matter; it is this which is no doubt present in the skins of many fruits, as for instance those of the grape; the exact nature of the chemical change is not clearly understood.

It is very obvious that the influence of light will convert starch into Chlorophyle. Every part of an amylaceous root becomes green on exposure to light. The parts of plants which become green (all without exception) contain starch; and in autumn as this green colour decreases the starch also decreases, and finally cannot be detected by the iodine-test. Hence starch ceases to form B. Chlorophyle under the influence of light, the B. Chlorophyle being a complex substance consisting chiefly of wax. The change of starch into B. Chlorophyle may be explained in much the same manner as its conversion into fat.

The wax contained in the leaves and other parts of plants may be chemically represented by the formula $C_{15}\ H_{15}\ O$. Now if no other products be simultaneously produced we may suppose the wax obtained from the starch in the following manner:—

5 equiv. of starch . . . . $C_{60}\ H_{50}\ O_{50}$
With 10 of water . . . . $H_{10}\ O_{10}$

Make . . . . $C_{60}\ H_{60}\ O_{60}$
And 4 of wax . . . . . $C_{60}\ H_{60}\ O_{4}$

Leaving to be given off . . . O_{56}

That is to say, 5 equivalents of starch yield 4 equivalents of wax, and give off 56 equivalents of oxygen. This fully explains the phenomenon why plants, while becoming green, evolve oxygen, and further indicates the use of starch in the leaves.

Mulder has, as far as we are aware, made only one ultimate analysis of pure C. Chlorophyle—that from poplar leaves; from this analysis he calculated the formula $C_{18}\ H_{9}\ N\ O_{8}$.

"Properly speaking," Mulder observes, "the green colouring-matter in the leaves has nothing to do with the evolution of oxygen; on the contrary, the colourless C. Chlorophyle, which seems to be every where present, becomes green by the absorption of oxygen. Hence a small portion of the oxygen produced from the conversion of starch into wax is employed for this purpose, and is not mixed with the atmosphere. But this is just the reason why C. Chlorophyle is not formed by the exhalation of oxygen; it only becomes green instead of white, as it previously was. This can only happen when there is an abundance of oxygen, and this we have seen to be the case when starch is converted into wax. We may therefore assume as proved that white Chlorophyle diffused throughout the whole plant, will become green in proportion as starch is converted into wax; because it is enabled, in such proportion, to take up oxygen—to become oxidised, just like white indigo.

"Now, the probable composition of green Chlorophyle,—$C_{18}\ H_{9}\ N\ O_{8}$ shows that pure white Chlorophyle is not produced from starch. It is necessary that an azotised body in a liquid state should penetrate into the globule of starch, which during this transformation into wax is converted into $C_{18}\ H_{9}\ N\ O_{8}$. We do not know yet what that substance is, but it is certain that it must be one which is diffused throughout the plant like starch; hence it is probably protein, which is changed into a most beautiful violet-coloured substance by the influence of hydrochloric acid and oxygen."

At one time it was supposed that the possession of Chlorophyle was characteristic of the vegetable kingdom. The following remarks however of Schultz, in the 'Comptes Rendues' for May 1852, would seem to indicate that the green colouring-matter of some animals closely approaches that of plants. He enumerates several animals of a green colour which are common in ditches and marshes, such as *Hydra viridis*, several green *Turbellarieæ*, *Vortex viridis*, *Mesotomum viridatum*, and *Derostomum cæcum*, and also several green *Infusoria*, such as *Stentor polymorphus*, *Ophrydium versatile*, and *Bursaria vernalis*. The colour in these animals is afforded by minute green globules, about 0·016 inch in diameter, which are situated under the integument in the parenchyma of the animals. They are perfectly spherical, and exhibit within the green substance an extremely minute colourless and homogeneous nucleus; or they may consist of several minute green globules, grouped together in a mulberry form. In this latter case they arise from the division of a homogeneous vesicle. This green colouring substance is not altered by dilute acids or alkaline solutions, by which it is distinguished from the green colouring-matter of several *Algæ*, which according to Nägeli is changed into yellow, orange, or red by the same reagents. Concentrated sulphuric and muriatic acids dissolve the colouring-matter: the solution is of a beautiful green or bluish-green colour, unchanged by the action of heat; it is also dissolved by a concentrated solution of potass, by ammonia, alcohol, and ether, the colour precisely resembling that of a solution of Chlorophyle. Its development also is influenced in the same way as that of vegetable Chlorophyle by light; but animals containing it do not evolve oxygen, and the author thence concludes that the evolution of that gas is not solely dependent upon the Chlorophyle in plants. In *Vortex viridis* the minute green globules, owing to their mutual compression, assume a hexagonal form; the green compartments thus formed are separated by an interstitial colourless substance. The existence of a colourless membrane around each vesicle may thence be deduced. This fact is further demonstrated in vesicles the green matter of which only partially fills the globular cavity.

With respect to the chemical composition of the membrane and of the nucleus of the vesicles in *Vortex viridis*, the results of the author's researches are limited to the following facts:—the solution of potass, and of ammonia and sulphuric acid, after the extraction of the colouring-matter, causes the membrane to swell out, in which the nucleus can no longer be recognised. The membrane becomes pale, and finally disappears entirely, but especially so after long boiling. Acetic and chromic acids and alcohol do not affect the membrane and the nucleus. By solution of iodine the vesicle is coloured brown, the nucleus becomes more distinct, but its colour is unaltered. It cannot consequently be assimilated to the nucleus of the vegetable chlorophyle vesicle, which most frequently consists of amylum.

CHLOROPHYLLITE, a Mineral occurring in 6- and 12-sided prisms, highly foliated, parallel to the base. The folia are soft and brittle, the lustre pearly, the colour grayish-green to dark-olive green. It has the following composition:—

Silica	45·2
Alum	27·6
Magnesia	9·6
Protoxide of Iron	8·2
Protoxide of Manganese	4·1
Water	3·6

It fuses only at the edges, and yields water before the blow-pipe. It occurs with *Iolite* in granite in the United States. A variety under the name of *Esmarkite* is brought from Brevig in Norway. *Fahlunite*, *Gigantolite*, and *Aspasiolite* are allied to this mineral, and like it probably proceed from the alteration of *Iolite*.

CHLOROSPERMEÆ. [ALGÆ.]

CHLOROSPINEL. [SPINEL.]

CHOANITES, a group of Spongoid Fossils from the Chalk of England and France, thus named by Mantell. Analogous living forms occur on the coast of Australia.

CHOCOLATE-TREE. [THEOBROMA.]

CHŒROPOTAMUS, a genus of extinct *Mammalia* belonging to the order *Pachydermata*.

C. Cuvieri (Owen). This animal, the remains of which have been found in the gypsum beds of Montmartre, Paris, and the Eocene Formations of the Isle of Wight, seems to have resembled the Peccari, but must have been about one-third larger, and was the earliest form of the Hog-Tribe introduced upon our planet. Cuvier was the first to recognise the distinct characters of this animal from the remains found at Paris. They were subsequently much more clearly defined by Professor Owen from the portions of the animal discovered in the Isle of Wight. The *Chœropotamus* is one of the links between the existing *Hippopotamus* and Hog-Tribe. Professor Owen in his 'British Mammals and Birds,' remarks, "Nothing as yet is known of the incisors of the *Chœropotamus*, the rest of the dentition closely resembles that of the Peccari; but the premolars are more simple, and the canines by their size, shape, and direction, and the lower jaw by the backward prolongation of its angle, alike manifest a marked approximation to the Ferine type. The occasional carnivorous properties of the common Hog are well known, and they correspond with the minor degree of resemblance which this existing pachyderm presents to the same type. The extinct *Chœropotamus*, still better adapted by its dentition for predaceous habits, presents an interesting example of one of those links, completing the chain of affinities which the revolutions of the earth's surface have interrupted as it were, and for a time concealed from our view." Other links in this chain of affinity are the genera *Anthracotherium* (Cuvier), *Merycopotamus*, and *Hippophyus* (Cautley and Falconer).

CHOIROPOTAMUS, a genus of Hogs found in Africa. [SUIDÆ.]

CHOLÆPUS, Illiger's generic name for the Two-Toed Sloths. [BRADYPUS; EDENTATA.]

CHOLESTERIN, a crystalline matter formerly known as a biliary fat, and supposed on account of its occurrence in biliary concretions to be especially connected with the secretion of the liver. It separates from its solutions in nacreous scales, which under the microscope appear in very thin rhombic tablets. It fuses at 145°, becoming solid and crystalline at 135°. It is found to consist of Carbon, Hydrogen, and Oxygen (C_{37} H_{32} O). In order to prepare it artificially gall-stones should be boiled in alcohol, when the Cholesterin is deposited by evaporation and cooling. Although when dissolved it is not easily detected in the fluids of the body, its presence is easily detected by the form of its crystals.

Small quantities of Cholesterin occur in most of the animal fluids. It is constantly present as a normal constituent of the bile, and also of the blood. The quantity in blood averages 0·088 in 1·000 parts.

It is often found as a morbid product in the body. Its mode of formation is unknown.

CHOMATODUS, a genus of Fossil Fishes from the Mountain Limestone of Bristol and Armagh. (Agassiz.)

CHOMORO. [PODOCARPUS.]

CHONDRILLA, a genus of plants belonging to the natural order *Compositæ* and the sub-order *Asteraceæ*, one species of which, *C. juncea*, yields a gum.

CHONDRITES. A Fossil Fucoid from the Greensand, named *Fucoides Turgionii* by Mantell, is thus entitled by Sternberg. ('Flora der Vorwelt.') It is very widely disseminated in the Greensand deposits of Europe. *Fucoides intricatus* of Brongniart belongs also to the Lower Cretaceous system in the Alps and Carpathians.

CHONDRODENDRON, a genus of plants belonging to the natural order *Menispermaceæ*. One species, *C. convolvulaceum*, is employed as a febrifuge in Peru. Endlicher states that the bark of some of the species is used for dyeing yellow.

CHONDRODITE, a Mineral, containing—

Silica	33·1
Magnesia	55·5
Protoxide of Iron	3·6
Fluorine	7·6

It occurs usually in imbedded grains or small rounded or flattened kernels or nodules in limestone, and appearing brittle. The colour is brownish-yellow or brown. The lustre vitreous. It is translucent or subtranslucent, with an uneven fracture. Hardness, 6 to 6·5; specific gravity, 3·1 to 3·2. It has also been called *Brucite*. Found in granular limestone in the United States.

CHONDROPTERYGII, or CARTILAGINEI, one of two great sections into which the class of Fishes is divided.

In this section we find species which possess, in most respects, the highest degree of organisation, while others possess the lowest observed in the class.

The principal character which distinguishes this section from the fishes with true bone (which usually come first in arrangement) is the cartilaginous substance of which the bones are composed, a circumstance arising from the very small quantity of earthy matter which enters into their composition. This earthy matter, when observed, is found to be disposed in small granules and not in distinct fibres, as in the first section.

The cranium of these fishes is not divided by true sutures, but is formed of a single piece: the maxillary and intermaxillary bones are either wanting or rudimentary, and their functions are performed by bones analogous to the palatines, and sometimes the vomer. Many of the vertebræ are often consolidated. The gelatinous substance, which in most fishes fills the intervals between the vertebræ (these intervertebral masses being connected only by a small cord), in this section frequently forms a thick cord, which varies but slightly in diameter.

In the Myxine (*Gastrobranchus cæcus*) no distinct vertebræ are perceivable, their place being occupied by a soft gelatinous tube. In the extraordinary little fish described by Mr. Yarrell in his 'History of British Fishes,' the Lancelet (*Amphioxus lanceolatus*), this part is still more rudimentary, consisting only of a slender transparent column. [BRANCHIOSTOMA.]

The *Chondropterygii* are divided by Cuvier into two orders—those which have their gills free, as in the generality of fishes; and those in which they are fixed—that is, the external edge attached to the skin. In the former of these orders the species have but one external gill-opening, and in the latter they have several—generally five. These orders are divided into families and genera, as follows:—

Order 1. *Chondropterygii.* With free Gills.
Family 1. *Sturionidæ* (Sturgeons).
Genus 1. *Accipenser.*
„ 2. *Spatularia.*
Family 2. *Chimæridæ.*
Genus 1. *Chimæra.*
Order 2. *Chondropterygii.* With fixed Gills.
Family 1. *Squalidæ* (Sharks, &c.).
The principal genera are:—
Squalus.
Zygæna (Hammer-Headed Sharks).
Squatina (Angel-Fish).
Pristes (Saw-Fish).
Family 2. *Raiidæ.*
Principal genera:—
Torpedo (Electric Rays).
Raia (Skate-Fish).
Trigon (Sting-Rays).
Mylobates (Eagle-Ray).
Cephaloptera.
Family 3. *Pteromyzidæ* (Lampreys, &c.).
Genus 1. *Pteromyzon.*
„ 2. *Ammocœtes.*
„ 3. *Gastrobranchus.*
„ 4. *Amphioxus* (*Branchiostoma*).

CHONDROSE'PIA, Leukard's name for a genus of *Cephalopoda.* [TEUTHIDÆ.]

CHONDRUS. [ALGÆ.]

CHONDRUS, a Pulmoniferous Mollusk. [PULMOBRANCHIATA.]

CHORDARIACEÆ. [ALGÆ.]

CHOUGH. [CORVIDÆ.]

CHRISTIANITE, another name for *Anorthite.* [ANORTHITE.] It has also been applied to a mineral allied to *Phillippsite.* [PHILLIPPSITE.]

CHRISTMAS-ROSE. [HELLEBORUS.]

CHRISTOPHER, HERB. [ACTÆA.]

CHROMIRON. [CHROMIUM.]

CHRO'MIS, a genus of Fishes. [LABRIDÆ.]

CHROMIUM, a Metal. It does not occur pure in nature. The following are the most important ores containing Chromium:—

Chromate of Lead. *Red Lead.* Occurs massive and crystallised. Primary form of the crystal an oblique rhombic prism. Colour deep orange-red. Lustre adamantine, sometimes translucent, rarely transparent. Specific gravity, 6. Hardness, 2·5 to 3. Brittle; streak orange-yellow. Cross-fracture uneven, passing into conchoidal, with a splendent lustre. With the blowpipe it crackles and melts into a grayish slag. Soluble in nitric acid; solution yellow. Occurs in the gold mine of Berezof in Siberia, in the Ural, and Brazil.

When pure it is composed of—

Chromic Acid	31·71
Oxide of Lead	68·29
	100

Massive varieties amorphous; structure columnar, granular.

Subsesquichromate of Lead. *Monochroite.* Occurs massive and crystallised. Form of the crystal imperfectly described. Colour red. Lustre resinous; translucent on the edges. Specific gravity, 5·75; very soft. Powder tile-red.

Fuses by the blowpipe into a dark mass. Occurs with Chromate of Lead in the Ural. It is composed of—

Chromic Acid	23·31
Oxide of Lead	76·69
	100

Chromate of Lead and Copper. *Vauquelinite.* Occurs massive and in minute crystals. Primary form an oblique rhombic prism. Colour black or greenish-black. Lustre adamantine, nearly opaque. Specific gravity, 5·5 to 5·78. Hardness, 2·5 to 3. Streak greenish. Fracture uneven.

Before the blowpipe it fuses into a dark gray globule of metallic lustre, surrounded with beads of metallic lead.

The massive varieties are amorphous, botryoidal, reniform. Structure compact, fine granular.

Found with Chromate of Lead in Siberia.

Composed of, according to Berzelius,—

Chromic Acid	28·33
Oxide of Lead	60·87
Oxide of Copper	10·8
	100

Chromate of Iron. *Chromiron.* Occurs massive and crystallised. Crystal the regular octahedron. Colour blackish; lustre imperfect metallic; opaque. Hardness, 5·5; brittle. Specific gravity, 4·321. Streak brown. Fracture uneven, imperfect conchoidal. Not attracted by the magnet. Cleaves parallel to all its planes.

Analysis of the crystals from Baltimore, by Dr. Thomson:—

Green Oxide of Chromium	52·95
Peroxide of Iron	29·24
Alumina	12·22
White matter	3·09
Water	0·70
A trace of Silica	
	98·20

The massive is amorphous, with a granular or compact structure. It is found in the island of Unst, in Scotland, and sometimes interspersed with green oxide: it occurs also in France and in North America, especially near Baltimore. Oxide of Chromium has been observed in some aërolites.

CHRYSALIS. [PUPA; INSECT.]

CHRYSANTHEMUM, a genus of plants belonging to the natural order *Compositæ* and the sub-order *Corymbiferæ* or *Asteraceæ.* This genus is known by the receptacle being without scales, the heads of flowers heterogamous, the flowers of the ray containing pistils and those of the disc both stamens and pistils; the involucre hemispherical; the fruit terete, without wings, no pappus; the flowers of the ray ligulate, those of the disc tubular. The species are very numerous in the temperate parts of the earth.

C. Sinense is most extensively cultivated in our gardens. [CHRYSANTHEMUM, in ARTS AND SC. DIV.]

There are two British species:—

C. leucanthemum, Ox-Eye or Ox-Eye Daisy. It is very common in our fields, and is known by the large white ligulate flowers of the ray, and the yellow tubular ones of the disc.

C. Segetum, the Corn-Marigold. It is common in corn-fields, and is easily distinguished from the last species by the flowers of the ray being yellow instead of white.

CHRY'SAOR, one of the numerous genera into which De Montford divided the Belemnites.

CHRYSA'ORA. [ACALEPHÆ.]

CHRYSI'DIDÆ, a family of Hymenopterous Insects of the section *Pupivora.* Distinguishing characters:—No nervures to the under wings; terminal segments of the abdomen forming a jointed retractile ovipositor; abdomen of the females with only three or four distinct segments, concave or flat beneath; antennæ 13-jointed in both sexes, and geniculated; mandibles slender, curved, and pointed; maxillary palpi filiform, generally longer than the labial palpi, and 5-jointed; the labial palpi are generally 3-jointed.

The *Chrysididæ* are most of them, if not all, of parasitic habits, that is to say, they seek the nests of other insects where they deposit their eggs to the destruction of the rightful owners; each species of this family apparently confining its attacks to the nest of some other hymenopterous insect, and generally selecting those of the same species. They are all of brilliant colouring, very active, and fly about in the sunshine; some are seen upon flowers, and most of them upon old walls, palings, and sand-banks. Some of these species are called Ruby-Tail Flies.

Chrysis ignita will afford a good illustration of this family. This insect is rather less than half an inch in length, has the head, thorax, and legs of a rich blue or green colour, and the abdomen of a burnished golden-copper hue; this part is truncated at the apex, and furnished with four little spines.

It will be perceived that the above is a description of a little four-winged fly, which so often attracts our notice from its brilliant colouring, and is so common on our garden walls when the sun is on them. This little insect is in constant motion, for if it ceases running or flying for a moment its little horns still keep up their vibratory motion. If we watch one of these insects for a short time, we perceive that it thrusts its head into every little hole in the brick-work; it is then searching after the nest of a wasp-like insect which builds in these situations.

The principal genera comprised in the family *Chrysididæ* are *Panorpes, Chrysis, Stilbum, Hedicrum, Elampus,* and *Cleptes.* An account of the habits of one of the species of *Panorpes* is given under the head BEMBEX, where the habits of *B. rostrata* are given, that being the species whose nests are subject to the attacks of the *Panorpes* which we are about to describe.

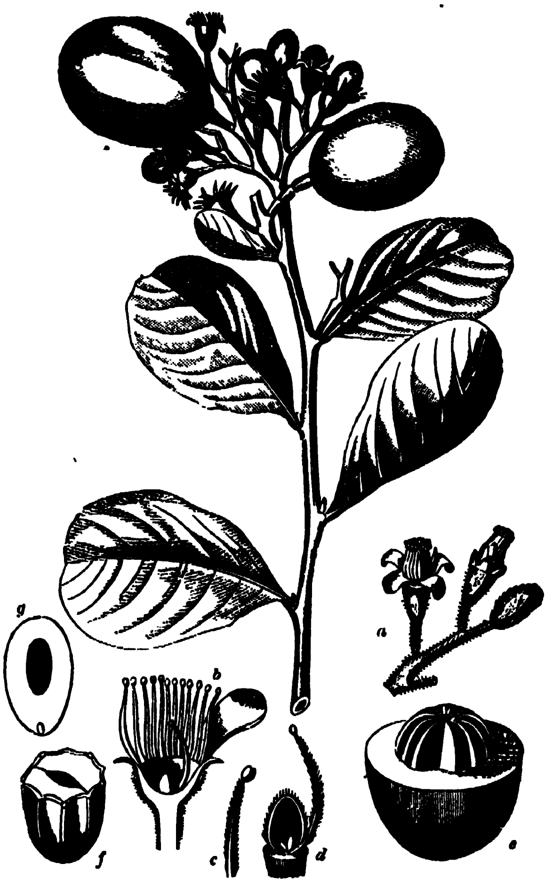
The genus *Panorpes* is distinguished from the other genera above mentioned principally by the elongated maxilla and labium, which appear like a proboscis, and the palpi being very small and two-jointed. *P. carnea* is about half an inch in length, and considerably broader than the *Chrysis ignita* (above described); the head, thorax, and base of the abdomen are of a blue-green colour; the remainder of the abdomen and the legs (with the exception of the thighs, which are blue) are of a reddish-yellow colour. It is found in various parts of Europe.

The characters of the genus *Chrysis* are:—Maxillary palpi 5-jointed, and longer than the labial; labial palpi 3-jointed; thorax not narrowed in front; labium rounded. About six or seven species of this genus are natives of England. *C. bidentata* is rather less than *C. ignita,* and differs from that species in having the thorax as well as the abdomen of a rich copper-like hue: the latter however has the apex blue. *C. cyanea* is entirely of a blue colour.

CHRYSOBALANA'CEÆ, *Chrysobalans*, a natural order of Polypetalous Exogenous Plants, allied to *Rosaceæ* and *Fabaceæ* (*Leguminosæ*), from which it differs in the style proceeding from the base of the ovary, and in its stamens being very irregular, often placed only on one side of the ovary. They are trees or shrubs, with alternate stipulate simple leaves, and flowers in loose racemes, corymbs, or panicles. Many species have no petals. They are exclusively natives of the tropics, where they often bear the name of plums. The gray or rough-skinned plums of Sierra-Leone are produced by species of *Parinarium*, and the Callimato, or Cocoa-Plum of the West Indies belongs to *Chrysobalanus Icaco*. [CHRYSOBALANUS.] The drupes of *Moquilla grandiflora* are edible. The order contains 11 genera and 50 species.

CHRYSOBALANUS, a genus of plants belonging to the natural order *Chrysobalanaceæ*. It has a campanulate 5-cleft calyx. Petals 5, unguiculate. Stamens about 20, nearly equal in length, disposed in one series. Drupe fleshy, plum-formed, containing an ovate 5-furrowed 1-seeded nut. Trees with simple leaves, and racemes or panicles of insignificant flowers. The fruit of all the species is edible.

C. Icaco, Cocoa-Plum, has nearly orbicular or obovate leaves, emarginate; racemes axillary, dichotomous; stamens hairy. It is a native of South America and the West Indies, by the sea-side, as well as of the southern parts of North America. The flowers are white. The fruit is about the size of a plum, ovate, roundish, varying much in colour, white, yellow, red, but most commonly purple, and usually covered with a sort of bloom. The skin is thin and the pulp white; the taste sweet, with some sharpness, but not unpleasant. It is eaten both raw and preserved. The root, bark, and leaves are used in medicine.



Cocoa-Plum (*Chrysobalanus Icaco*).

a, Flowers in different stages of development; *b*, vertical section of the flower; *c*, stamen; *d*, vertical section of the pistil, showing the ovules in the base of the ovary; *e*, horizontal section of fruit, showing the inclosed nut; *f*, transverse section of nut; *g*, a cotyledon, with the plumule at its base.

C. ellipticus, Elliptic-Leaved Cocoa-Plum, has elliptic leaves, obtuse or acute, never emarginate; racemes axillary, dichotomous; stamens hairy. It is a native of Sierra-Leone on the sea-side. The fruit is about the size of a damson, and like the other species is eatable.

The other species are—*C. oblongifolius*, Oblong-Leaved Cocoa-Plum, native of Brazil; *C. ovalifolius*, Oval-Leaved Cocoa-Plum, a shrub, native of Brazil; and *C. macrophyllus*, Large-Leaved Cocoa-Plum, also a native of Brazil.

The species thrive best in sandy loam. The best mode of increasing the plants is by seeds, when they can be procured.

CHRYSOBERYL, a Mineral called *Cymophane* by Haüy. It occurs massive and crystallised. Primary form, a right rhombic prism. Its colour is green, sometimes with a yellow or brown tinge, with occasionally a blue opalescence. Streak white. Lustre vitreous. It is translucent or transparent. Specific gravity about 3·8. Hardness, 8·5. Fracture conchoidal. Before the blowpipe it suffers no change alone; with borax it fuses into a transparent glass.

The massive variety occurs in rounded pieces.

It is found in Brazil, and in Connecticut, North America.

Seybert first found that it contained glucina. The following are his and Dr. Thomson's analyses :—

Seybert.		Thomson.	
Alumina . . .	73·60	Alumina . . .	76·752
Glucina	15·80	Glucina . . .	17·791
Silica . . .	4	Protoxide of Iron .	4·494
Protoxide of Iron . .	3·38	Volatile matter . .	0·480
Oxide of Titanium .	1		
Moisture . . .	0·40		99·517
	98·18		

CHRYSOCHLO'RA, a genus of Dipterous Insects belonging to the family *Stratiomydes*. Characters :—Body elongated; antennæ with the basal joint short, the third long, conical, and compressed; stylet terminal, elongated; third posterior nervure of the wings not reaching the hinder margin.

C. amethystina is about three-quarters of an inch in length; the head and antennæ are black; there is a white spot at the base of each antenna; the thorax and abdomen are of a violet-blue colour, the latter has a yellow spot on each side of the second, third, and fourth segments; the legs are black.

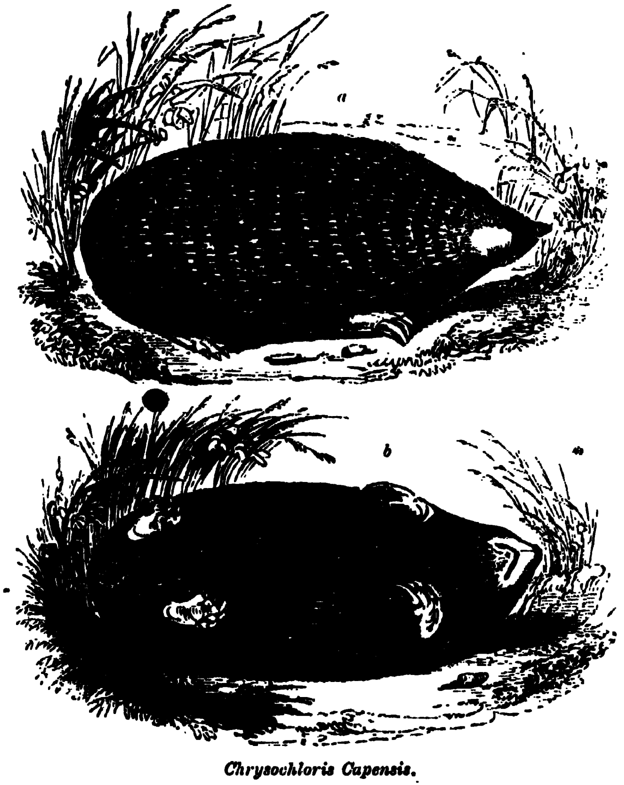
It inhabits the island of Mauritius and the East Indies.

CHRYSOCHLO'RIS (Lacépède), a genus of animals belonging to the class *Mammalia*, and allied to the Moles (*Talpa*), but differing from them in their dentition and in other particulars. Dental formula :—

Incisors, $\frac{2}{4}$; canines, 0; molars, $\frac{9-9}{8-8}$ = 40. The true molars are long, distinct, and nearly all in the shape of triangular prisms.

The muzzle is short, wide, and reflected. There is no external ear, nor any appearance of the eye externally. The fore feet have three claws only; the exterior claw is very large, arched, and pointed, forming a powerful instrument for penetrating and digging the earth; the other two diminish gradually. The hind feet are furnished with five claws of ordinary size. The fore-arm is supported by a third bone placed under the ulna to strengthen it when the animal is employed in excavation. The body is thick and short. The hair, or rather fur, which is thick set, has a metallic lustre.

C. Capensis, Desmarest; Taupe Dorée of the French; *Talpa Asiatica* of Linnæus; *C. villosa* of A. Smith. Hair brown, presenting in certain lights very brilliant changeable green, bronze, and coppery tints. Cuvier says that it is the only quadruped whose covering reflects those metallic tints which render so many birds, fishes, and insects brilliant. There is no apparent tail.



Chrysochloris Capensis.

a, the animal on its feet; *b*, the same turned up to show the claws, &c.

This creature inhabits the Cape of Good Hope, where it is said to live much in the same way as the mole, and to prey like it upon worms, &c.

C. holosericia, the Changeable Mole, is a species also found at the Cape.

CHRYSOCO'LLA (from χρυσὸς, gold, and κόλλα, glue), is a name which the Greeks appear to have applied to Borax, perhaps from its use as a flux in melting gold.

CHRYSOCOMA, a genus of plants belonging to the natural order *Compositæ*. *C. Linosyris*, a British plant, is now referred to *Linosyris*. [LINOSYRIS.]

CHRY'SODON (Oken), a name given to the *Pectinaires* of Lamarck, the Amphictènes of Savigny, and the *Cistenes* of Dr. Leach, forming a part of the genus *Amphitrite* of Cuvier. [ANNELIDES.]

CHRYSOGA'STER, a genus of Dipterous Insects of the family *Syrphidæ*. Characters :—Body much depressed ; no false nervures to the wings ; third joint of the antennæ oval or orbicular.

About fourteen species of this genus have been discovered in England ; they are all of moderate size, and their colouring is metallic. *C. splendens* is about one-third of an inch in length ; the head is green ; antennæ yellow ; thorax golden-green ; abdomen purple-black, greenish towards the sides ; the legs are black ; wings brownish. This and all the other species recorded as British have been found in the neighbourhood of London.

CHRYSOLITE, a Mineral called *Peridot* by Haüy. *Olivine* is a variety of this mineral, and *Chusite* also, according to Dr. Thomson.

It occurs massive and crystallised. Primary form a right rhombic prism. Colour green, sometimes brownish or yellowish ; streak white. Lustre vitreous, translucent, transparent, double refracting. Specific gravity, 3·33 to 3·41. Hardness, 6·5 to 7. Fracture conchoidal.

The massive varieties are amorphous, granular.

The *Chrysolite* used in jewellery is brought from the Levant, and is supposed to be found in Upper Egypt. The variety on account of its colour called *Olivine*, occurs in basalt in Bohemia, Hungary, and on the banks of the Rhine. The following are analyses :—

	Klaproth.	Vauquelin.
Silica	39	38
Magnesia	43·5	50·5
Protoxide of Iron . . .	19	9·5
	101·5	98·0

Some varieties contain small portions of alumina and of the oxides of nickel and manganese. It does not fuse or lose its transparency before the blow-pipe. With borax it fuses into a coloured glass, and with soda into a brown scoria.

CHRYSOME'LIDÆ, a family of Coleopterous Insects of the section *Cyclica*. Characters :—Antennæ wide apart at the base, and inserted before the eyes ; body generally short and convex ; tarsi short and rather broad, 4-jointed, the penultimate joint bilobed ; all the joints, excepting the terminal joint, covered beneath with a velvet-like substance.

The *Chrysomelidæ* constitute a very numerous and beautiful family of the Beetle Tribe : they are generally of moderate size, and frequently very brilliant in colouring.

Between seventy and eighty species have been discovered in England, and the number of species contained in collections from various parts of the world may probably amount to four or five hundred.

This group may be divided into two sections : those in which the head is hidden beneath the thorax, and the body is frequently somewhat cylindrical ; and those in which the head projects from the thorax so as to be distinctly seen when the insect is viewed from above, and where the body is generally rounded, or oval, and convex.

The first of these sections may again be readily subdivided according to the proportions of the antennæ. In some the antennæ are short, and more or less serrated ; here belong the genera *Clythra*, *Lamprosoma*, and *Chlamys*. The species of this last genus are among the most remarkable of Coleopterous Insects. They are of small size, the largest being about half an inch in length, and the thorax and elytra are generally very uneven, and studded with numerous angular projections. This circumstance, together with the extremely brilliant colouring with which they are adorned, has caused them to be compared to pieces of minerals ; indeed, one which is now before us, and which is of a beautiful red hue, we have known to be mistaken at first sight for a piece of copper-ore. Most of the species of *Chlamys* inhabit Brazil, and none are found out of the western hemisphere. The generic characters are :—Head vertical ; thorax humped ; the posterior margin produced in the region of the scutellum ; body somewhat cube-formed ; antennæ with the basal joint rather long, the second very small ; the remaining joints dilated, and more or less serrated ; labial palpi sometimes forked.

The remainder of the *Chrysomelidæ* of the first section have the antennæ long and slender. The genera are *Cryptocephalus*, *Choragus*, *Euryope*, and *Eumolpus*.

The second section, or those in which the head is apparent when the insect is viewed from above, comprises the genera *Colaspis*, *Podontia*, *Phyllocharis*, *Doryphora*, *Cyrtonus*, *Paropsis*, *Apamæa*, *Timarcha*, *Chrysomela*, *Phædon*, and *Prasocuris*.

The genus to which the name *Chrysomela* is now restricted, is principally distinguished by the following characters :—Maxillary palpi with the terminal joint as large or larger than the preceding one, and of the form of a truncated cone, or nearly oval ; the elytra are separate, that is, not joined at the suture ; no sternal projection.

Upwards of forty species of this genus have been discovered in England.

C. Banksii is one of the largest species of the genus : it is rather less than half an inch in length, and of a brown colour with a metallic lustre ; the thorax has an indentation running parallel with and close to the lateral margins ; the elytra are coarsely punctured ; the legs and antennæ are ochre-coloured. It is found on nettles in the neighbourhood of London and elsewhere, but is rather local. *C. sanguinolenta* is about three-eighths of an inch in length, and of a dull blue-black colour ; the elytra are rather rough. *C. Graminis* is about the same size as the last, and of a bright-green colour ; this species is abundant in various parts of Cambridgeshire. *C. polita* is about a quarter of an inch in length, and very glossy ; the head, thorax, and legs are green, and the elytra are of a reddish-ochre colour. This species is very common in marshy situations. *C. cerealis* is about the same size as *C. sanguinolenta*. This is one of the most beautiful species of the genus. It is tolerably common in France and Germany, but till found on the summit of Snowdon (about twenty years ago), was scarcely known as a British insect. It is very glossy ; the legs, antennæ, and under parts are blue ; the elytra are adorned with longitudinal stripes of blue, green, and red ; and the same colours are observed on the head and thorax. *C. Goettingensis* is of a purple colour, and the elytra are very finely punctured. This species is very common in chalk districts. [CYCLICA.]

CHRYSO'PHILA, a genus of Dipterous Insects. [LEPTIDES.]

CHRYSO'PHORA, a genus of Coleopterous Insects of the section *Lamellicornia* and family *Xylophili*. The principal generic characters consist in the immense size of the hind legs of the males. The sternum is produced into a somewhat pointed process between the second pair of legs ; the posterior thigh of the male is very thick ; the tibiæ are curved, and produced at the apex internally into a long bent process ; the hind legs of the female are thick, but comparatively short, and the hinder tibiæ are abruptly terminated ; the outer claws of all the tarsi are larger (in both sexes) than the inner ; they differ in the male, however, in being broader than in the female, and those of the anterior pair of legs are bifid ; their outer claws are very long, and the insect has the power of bending them under so as to fix their points beneath a projection of the fourth joint of the tarsus : they are probably used for clinging to the slender branches or leaves of trees.

But one species of this genus is known—*C. chrysochlora*. It is of a rich metallic green colour ; the head, thorax, and scutellum are shagreened ; the elytra are rugose throughout ; the tibia of the hind leg is of a brassy or copper-like colour ; all the tarsi are blue-black. The length of the hind leg of the male exceeds that of the body, which is about one inch and a half ; the female is rather less. This beautiful insect inhabits Venezuela.

CHRYSOPHRYS, a genus of Acanthopterygious Fishes belonging to the family *Sparidæ*. The body is deep, compressed ; dorsal fin single, the rays partly spinous, the posterior rays flexible ; teeth of two kinds, six incisors in each jaw, conical, with rounded and oval molar teeth in four rows above and three rows below ; cheeks and operculum with scales ; brachiostegous rays six.

C. aurata, Gilt-Head, is one of the fishes most abundant in the Mediterranean. From Gibraltar it is found as far south as the Cape of Good Hope, and northward along the coast of France and Spain. It has been recently taken on the British coasts. These fishes were so called by the Greeks on account of their golden-coloured eyebrows. They are said to spawn in the summer : their food consists of molluscous and testaceous animals. The Gilt-Head has peculiar rounded teeth. The body is deepest at the commencement of the dorsal fin. The head short and elevated ; the back silvery gray, shaded with blue ; the belly like polished steel, with longitudinal gold-coloured bands on the sides ; the fins are a grayish-blue ; the tail darker ; the dorsal and anal fins appear as if placed in grooves from the rising edges of the scales on each side. This fish seldom exceeds 12 inches in length.

CHRYSOPHYL'LUM, a genus of Plants belonging to the natural order *Sapotaceæ*. *C. Cainito* yields a West Indian fruit commonly called the Star-Apple. Like the rest of its kindred it abounds in a sweet harmless milky juice, that flows most copiously when the tree is beginning to mature its fruit, which grows on a moderately-sized spreading tree with very slender flexible branches. The leaves are dark-green on their upper surface, and are covered beneath with a remarkably satiny ferruginous pubescence. The flowers grow in small purplish bunches, and are succeeded by a round fleshy smooth fruit, resembling a large apple. In the inside it is divided into ten cells, each containing a black shining rhomboidal seed, and surrounded by a white, or sometimes purplish, gelatinous pulp, traversed with milky veins, and of a very sweet agreeable flavour. In an unripe state the taste is said to be astringent and unpleasant. When cut across, the seeds, which are regularly disposed round the axis of the fruit, present a stellate figure, from whence the name of Star-Apple is derived. There is a smaller species, which produces the fruit called the Damson-Plum. The tree is common in the hot-houses about

London, and is well represented in a fruit-bearing state in Sloane's 'Jamaica,' plate 229.

CHRYSOPLE'NIUM, a genus of plants belonging to the natural order *Saxifragaceæ*. It has a 4-fid half-superior calyx, no corolla, 8 stamens (rarely 10), 2 styles, a 1-celled capsule with two beaks opening in the form of a cup. There are two species of this genus found in Great Britain, and known under the name of Golden Saxifrage. One is *C. alternifolium*, and is characterised by alternate leaves. It has an erect stem 4 or 5 inches high, with umbellate, nearly sessile, deep yellow flowers. It is a native of boggy places. *C. oppositifolium* has opposite leaves. The stem is decumbent and straggling, about 6 inches long. The flowers are paler and more scattered than in the last species. The leaves are usually glabrous, but sometimes they are slightly hairy. It is a native of damp shady places. (Babington, *Manual of British Botany.*)

CHRYSOPRASE. [AGATE.]

CHRY'SOPS, a genus of Dipterous Insects of the family *Tabanidæ*. Characters:—Head hemispherical; antennæ elongated, second joint nearly as long as the first, both covered with fine hairs; third joint equal in length to the first and second taken together, and having five false joints or divisions; eyes of a golden green colour, with purple lines or spots.

Upwards of thirty species of this genus have been discovered.

C. cæcutiens is a British form. It is rather larger than the common house-fly, the expanded wings measuring about two-thirds of an inch. It is black; the male has a yellow spot on each side of the first segment of the abdomen; the female, in addition to these spots, has the second segment yellow, with two diverging black lines in the middle; the wings are whitish; the anterior border is broadly margined with black, and there is a broad black band near the middle: the wings of the male are nearly all black.

Most persons undoubtedly have been troubled more or less with the insect above described when walking in the country, especially in the neighbourhood of water. Three or four will sometimes settle on us at the same time, and if on the arm their presence is soon discovered by a sharp prick, caused by their thrusting the proboscis through the sleeve; the bite however is not venomous, and for the slight pain caused by it we are repaid by a sight of the little insect. Nothing can be more beautiful than its large eyes, which seem to reflect all the colours of the rainbow: they may be described as green with purple spots, but the green varies to golden and red hues in certain lights. When it first settles, this fly is not easily caught, but it soon becomes so engaged in its occupation that it may almost be touched before it will move.

CHUB. [LEUCISCUS.]

CHUSITE, a Mineral found by Saussure in the porphyritic rocks near Limburg. It occurs massive, granular, translucent, and of a greasy lustre. Dr. Thomson refers it to *Chrysolite*.

CHUSSALONGA. [EUPATORIUM.]

CHYDORUS, a genus of Entomostracous *Crustacea* belonging to the section *Branchiopoda*, the order *Cladocera*, and the family *Lynceidæ*. The species are nearly spherical in shape; the beak is very long and sharp, curved downwards almost into the shape of a crescent; the inferior antennæ are very short. There are two British species—

C. sphæricus, Baird (*Lynceus sphæricus*, Müller; *Monoculus sphæricus*, Gmelin; *Chydorus Mülleri*, Leach). It is very common in ponds and ditches all the year round. It has a round smooth shell, of an olive-green colour, slightly ciliated on the anterior margin. Through this shell can be seen its convoluted intestine. The eye is areolar, and the black spot accompanying it large. It rather rolls than swims through the water.

C. globosus, Baird, has a more globular shell, and is six times larger than the last. The shell is of a reddish hue, and has a large irregular dark band running across the centre of the shell. It is not so common as the last species.

CHYLE (χυλός), the product of digestion formed by the action of the pancreatic juice and the bile on the chyme in the duodenum. [DIGESTION.]

CHYME (χυμός), the product of digestion formed by the action of the stomach on the food. [DIGESTION.]

CICADARIÆ. [HOMOPTERA.]

CICADE'LLA, Latreille (*Cercopidæ*, Leach), a family of Insects of the order *Hymenoptera* and section *Cicadariæ*. This family is synonymous with the *Cicada Ranatra* of Linnæus. The species may be distinguished from those of allied groups by their having the antennæ situated between the eyes. These insects are generally small, and leap by means of their hind legs. The genera may be arranged under two heads or sections.

1. In the first section the head is hidden by the pro-thorax, which is always very large, generally much humped, and has the posterior portion produced over the abdomen, sometimes so as to completely cover that part, or even extend beyond its apex; the antennæ are very small, and inserted in a cavity on the head. To this section belong the genera *Membracis*, *Tragopa*, *Darnis*, *Bocydium*, and *Centrotus*.

There are perhaps no insects more remarkable in structure, and whose appearance is more grotesque, than most of the species of this group. Their peculiarity arises from the great development of the pro-thorax: this part is sometimes so large as greatly to exceed in size all the other parts taken together. We have selected for illustration two species of the genus *Bocydium*, as being the most remarkable; one of these is the *Bocydium tintinnabuliferum*. In this species the thorax is black and glossy; the posterior part is elongated and pointed, and from the disc there arises a vertical appendage, the summit of which bears four slender horizontal stalks, each of which is furnished with a little round black spherical body: these little globes are covered with fine hairs; the abdomen is reddish, and the wings are variegated with the same colour.

Fig. 1.

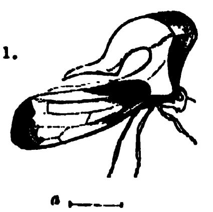


Fig. 2.

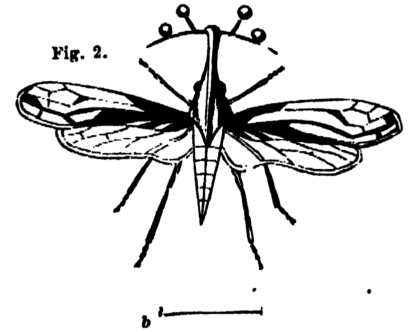

Fig. 1. *Bocydium galeritum*. *a*, Natural length.
Fig. 2. *Bocydium tintinnabuliferum*. *b*, Natural length.

The other species is the *Bocydium galeritum*. This species, as well as the one just described, inhabits Brazil; the pro-thorax is of a dark reddish-brown colour; the posterior part is elongated; the disc is elevated into a process which is at first compressed, but at the summit becomes dilated into a broad angular mass, and throws out a flattened portion, which suddenly bends downwards towards the body, and then runs parallel with it. The wings are transparent, with the exception of the basal and apical portion of the upper ones. The principal distinguishing characters of the genus *Bocydium* consist in the elytra being wholly or partially exposed, that is, not covered by the pro-thorax; and the posterior prolongation of the pro-thorax narrowed and pointed.

Of the genus *Centrotus* two species are found in England; the more common species is *Centrotus cornutus*. This little insect is found on the leaves of the hazel and other shrubs, in the early summer months. It is about one-third of an inch in length, and of a brown colour; the pro-thorax is prolonged posteriorly (this part is compressed and pointed, and extends nearly to the apex of the abdomen), and the sides are dilated, and form two horn-like projections: a character from which the insect has received in France the name of 'le petit Diable.' The wings are brownish and semi-transparent. In this genus the wings are exposed, as in the last, but the species differ in having a visible scutellum.

2. In the second section of the *Cicadellæ*, the head is on a line with the upper surface of the pro-thorax, or nearly so; the latter part is of moderate size, and without the extraordinary processes which characterise the former division—the wings are consequently always entirely exposed; the scutellum is distinct and of a triangular form. To this division belong the genera *Æetalion*, *Ledra*, *Ciccus*, *Cercopis*, *Eulopa*, *Euplex*, *Penthimia*, *Jassus*, *Tettigonia*, and some others.

Of the genus *Cercopis* (Latreille) we have many species in this country. They are all small. The largest and most beautiful of the British species is the *Cercopis vulnerata*. This insect is about one-third of an inch in length; black; the upper wings are obscure, and have each two large red spots (one at the base and another in the middle), and a fascia of the same colour near the apex, the black and the red being about equally divided; the under wings are transparent. This species is not uncommon in various parts of the country, and is found on the herbage in woods. *Cercopis spumaria* is one of the most common insects we have, being found in abundance on the various plants in our gardens. It is sometimes called the Frog-Hopper, from its habit of leaping when approached. Its colour is brown, the under wings are transparent, the upper wings have two white spots, one in the middle and another towards the apex. The larva in form resembles the perfect insect, except that it is destitute of wings; it is soft and of a greenish colour, and is always found on the leaves of plants, inclosed in a frothy liquid, with which it surrounds itself, probably as a protection against the sun's rays. This frothy liquid is commonly known in England by the name of Cuckoo-Spit, and in France it is called Crachat de Grenouille. The pupa differs only from the larvæ in having rudimentary wings; the perfect insect is about three-sixteenths of an inch in length.

The characters of the genus *Cercopis* are:—Antennæ with the third joint conical, and terminated by an inarticulate seta; head furnished with ocelli. This genus was established by Fabricius, and has lately been subdivided. The insect last described belongs to one of these sub-genera (*Aphrophora* of Germar), in which the head has the posterior margin concave, and the ocelli are more widely separated than in the genus *Cercopis* as now restricted. The characters of some other sub-genera will be found in a paper by Mr. Lewis, in the first part of the 'Transactions of the Entomological Society.'

The genus *Ciccus* differs from *Cercopis* principally in the species having the seta of the antennæ articulated, and composed of five joints; the anterior part of the head usually projects.

CICELY. [MYRRHIS.]

CICE'NDIA, a genus of plants belonging to the natural order *Gentianaceæ*. It has a 4-parted funnel-shaped corolla, without glands or any corona, eventually twisted over the capsule; the calyx 4-lobed, tubular; the stamens 4; the anthers erect, not twisted; the stigma capitate, undivided; the capsule single, or imperfectly 2-celled. The species of this genus were formerly referred to *Gentiana* and *Exacum*.

C. hyssopifolium has an herbaceous stem 4-sided, with the angles slightly winged; the flowers 6 or 8 together in axillary whorls, each furnished with a linear spathulate bract; the calyx 5-cleft, permanent, and closely embracing the base of the mature capsule. This is a common plant in many parts of the East Indies, and, like the whole of the order to which it belongs, the plant possesses a bitter principle, though not so intense as some of its allies. It is employed by the natives of India as a stomachic, and is administered in the form of decoction or powder. In addition to the tonic action, it is said to act as a laxative.

C. filiformis (*Exacum filiforme* of Smith and others) has the calyx 4-lobed, half-tubular, adpressed to the subglobose tube of the corolla; lobes ovate, acute; stem thread-shaped, forked; flowers solitary, on long stalks. It has yellow flowers, and is a native of Europe. It is found in damp sandy places in England and Ireland.

In their cultivation the species of *Cicendia* require the same treatment as Gentians.

(Babington, *Manual;* Lindley, *Flora Medica.*)

CICE'R, a genus of Leguminous or Fabaceous Plants allied to the Vetch. A 5-lobed calyx which projects on the upper side, and an inflated 2-seeded pod with tuberculated seeds, give its character. One species, *Cicer arietinum*, the Chick-Pea, a native of Egypt and the Levant, is cultivated in the south of France for its seeds, which bear a striking resemblance to a ram's head. They have for ages been a common food in the eastern parts of the world, but their taste is unpleasant to Europeans. It is an annual, and bears pale violet solitary flowers. Two or three other species are known to botanists.

The most remarkable circumstance about *C. arietinum* is, that during the heats of summer its leaves and stem exude little viscid drops, which, on evaporation, leave behind crystals, nearly pure, of oxalic acid. Its grateful refrigerating qualities are owing to this acid. Persons who walk through the fields where it grows, with common leather shoes, find them destroyed by the acid.

CICHORA'CEÆ, one of the primary subdivisions in the system of Jussieu of the natural order *Compositæ*. It is characterised by the absence of albumen in the seed; the seeds are erect, the corollas ligulate, the juice milky. The plants included under this division by Jussieu belong to De Candolle's *Liguliflorœ*. The *Cichoraceæ* in their anatomical structure closely resemble the *Campanulaceæ;* they also resemble that order in their physical properties. Both orders produce a milky juice, possessing in some species powerful medical properties. This juice in the *Cichoraceæ* has a bitter and astringent taste, and possesses narcotic properties. It is found in the *Cichorium Intybus*, the common Succory [CICHORIUM], and in the cultivated and wild Lettuce. [LACTUCA.] From the latter plants the juice has been obtained under the name of Lactucaricum, and used as a narcotic, instead of opium. Many of the species of *Cichoraceæ* secrete starch in large quantities, and are used as articles of diet, as the Endive, *Scorzonera*, *Tragopogon*, or Salsafy, &c. The root of the Dandelion (*Taraxacum Dens Leonis*) is used as a tonic and purgative, and has been recommended in disorders of the stomach. [LEONTODON.] The British genera of *Compositæ* belonging to this division are as follows:—

Section I. *Lapsaneæ.*
Lapsana.
Section II. *Hyoserideæ.*
Arnoseris.
Cichorium.
Section III. *Hypochærideæ.*
Hypochæris.
Achyrophorus.
Section IV. *Scorzonereæ.*
Thrincia.
Leontodon.
Oporinia.
Tragopogon.
Picris.
Helminthia.
Section V. *Lactuceæ.*
Lactuca.
Leontodon.
Barkhausia.
Crepis.
Sonchus.
Mulgedium.
Section VI. *Hieraceæ.*
Hieracium.

The geographical distribution of *Cichoraceæ* is generally similar to that of *Compositæ*, but they are found in greatest numbers in cold climates, and in this respect are the representatives of the *Corymbiferæ*, which are most abundant in hot climates. [CORYMBIFERÆ.]

(Lindley, *Natural System;* Babington, *Manual of British Botany.*)

CICHORIUM, a genus of plants belonging to the tribe *Cichoraceæ* and the natural family *Compositæ*. The species are known by the common names Chicory, Succory, and Wild Endive. De Theis derives the name from Chikouryeh, stated by Forskäl to be the Arabic name. The name Endivia seems to be derived from another Arabic name, Hindibeh. The genus *Cichorium* consists of only a few species found in the temperate parts of Asia, the Mediterranean region, and in Europe. It has a double involucre, of which the exterior is 5- and the interior 8-leaved, with the leaflets united at the base; pappus crown-like, formed of many paleæ, shorter than the achenium. Receptacle naked or pitted. Flowers blue.

C. Intybus, found in uncultivated places, dry pastures, and roadsides in Europe, has two or more heads of flowers, crowded, sessile or stalked, floral leaves lanceolate, subamplexicaul, broader at the base, pappus much shorter than the achenium.

C. Endivia, the Common Endive, cultivated throughout Europe, is supposed to have been introduced from India, where it is well known by its name of Kasnee. This species, like the former, has two or more heads, sessile or stalked, but with the floral leaves broad-ovate, cordate at the base and amplexicaul, pappus four times shorter than the achenium. [CHICORY; ENDIVE, in ARTS AND SC. DIV.]

CICINDE'LIDÆ, a family of Coleopterous Insects of the section *Adephaga* and sub-section *Geodephaga*. The true Carnivorous Beetles are included in a large section called *Adephaga*, all the species of which group may be distinguished by their having six palpi. The section *Adephaga* is divided into two sub-sections, the *Geodephaga* and the *Hydradephaga*. The former obtain their subsistence on the land, and the latter in the water. The structure of the insects in these two groups, in order to suit them to their habits, is therefore of necessity essentially different (as far as secondary characters of form, &c., are concerned), the former being formed for running and the latter for swimming. In the number of joints to the tarsi (which is always five), and the antennæ (which is eleven), and the parts of the mouth, they are however alike; these latter are generally considered primary characters. To make ourselves more clearly understood, we may compare the section *Adephaga* among Beetles to the *Carnivora* among the *Mammalia;* the *Geodephaga* to the bears, weasels, dogs, and cats; and the *Hydradephaga* to the seals and otters. We may again carry our simile further by comparing the *Cicindelidæ* to the cats or tigers, the beetles belonging to this family being pre-eminently voracious.

The *Cicindelidæ* are divided into two groups—those species in which the emargination of the mentum is furnished with a tooth or pointed process in the middle, and those in which this process is wanting. To the first group or section belong the genera *Manticora*, *Platycheile*, *Megacephala*, *Oxycheila*, *Iresia*, *Cicindela*, *Dromica*, *Euprosopus*, and *Ctenostoma;* and to the second section belong the genera *Therates*, *Tricondyla*, and *Colliurus*.

The typical genus of the family we are treating of is *Cicindela*, and in this genus, as is generally (if not always) the case in typical genera, the species have a wide geographical range, and are very numerous. Taking Dejean's 'Catalogue' as our guide, we find the genus *Cicindela* containing upwards of 200 species, and the number of species contained in all the other genera taken together is about forty. The species of *Cicindela* are found in every quarter of the globe, whereas the other genera mentioned are very local; they are all extra-European, some being entirely confined to Africa, several to South America, and others to India.

The technical generic characters of *Cicindela* are:—Labial palpi moderately long, in this respect not exceeding the maxillary palpi; last joint of all the palpi truncated at the apex, and about the same width as the preceding joints; three basal joints of the anterior tarsi dilated in the males, and covered beneath with a velvet-like substance.

As regards the form, the most striking character of the *Cicindelæ* is the great projection of the eyes; the jaws are very long and sharply pointed, and furnished on the inner side with three tooth-like processes; the head is generally equal in width to the thorax, or sometimes exceeding it; the thorax is either somewhat cylindrical or rather depressed and nearly square, and is transversely indented before and behind. The elytra are generally rather depressed, and almost double the width of the thorax; the legs and antennæ are long and slender.

The colouring of the *Cicindelæ* is generally rich and metallic; the upper surface is usually more or less shagreened, and hence is not glossy; the under surface is glossy, and generally sparingly covered with hairs of a pale colour.

With respect to their habits, it has been before remarked that the *Cicindelæ* are extremely voracious; we may add, they are very active, and almost always take to the wing when approached, and hence are caught with difficulty; their flight is however short. The situations which they inhabit are generally sandy plains or heaths, and sometimes the sea-shore or the shores of rivers, &c.; but some of the other genera of the *Cicindelidæ*, from their form and colouring, appear to be more particularly adapted to these last-mentioned situations.

Six species of the genus *Cicindela* have been found in England, of which the most common is *Cicindela campestris.* This insect is found more or less abundantly throughout the country, and is very common in the neighbourhood of London; it is rather more than half an inch in length, and of a bright green colour; the anterior and posterior margins of the thorax, the legs, and the basal joints of the antennæ are of a rich copper-colour; the under side of the body is glossy and of a blue-green colour; the wing-cases are each adorned with six cream-coloured spots, one on the shoulder or outer angle, another at the apex, three on the outer margin at nearly equal distances apart, and one on the disc, a little lower down than the third marginal spot from the shoulder.

The larva of this insect is very well known, and may be found almost at any time during the summer in sandy situations. It lives in cylindrical burrows, varying from six inches to a foot in depth, these burrows being excavated by itself. Like the perfect insect, it is very voracious, and in fine weather may be seen with its head on a level with the surface of the soil, lying in wait for any insect which may happen to crawl over its cell. Its form is remarkable: the head is very large and slightly concave; the jaws are also large and curved upwards; the body is furnished with six legs, attached to the first three segments, and is humped near the middle of the back, at which part there are two tubercles, each of which is furnished with a horny hook; these hooks and the body being naturally of a bent shape, enable the animal to sustain its position at the top of the cell, or to ascend and descend very quickly: the concave head and the recurved mandibles form a kind of natural basket, in which the soil is brought to the mouth of the cell during the progress of its excavation.

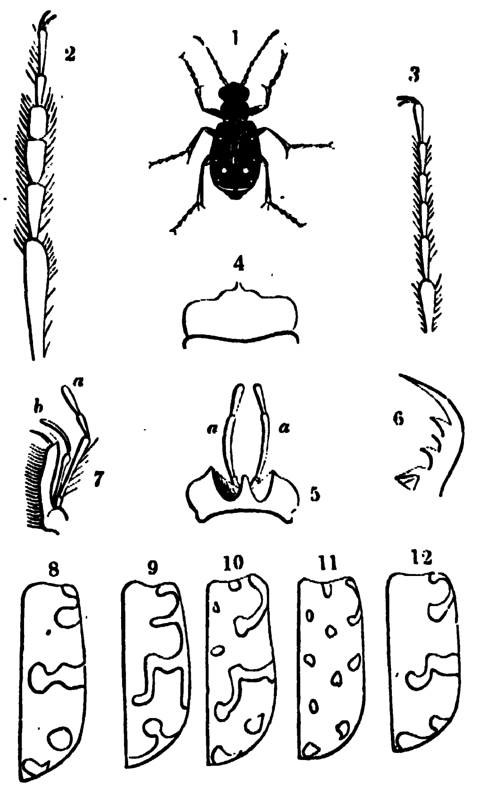

Fig. 1, *Cicindela campestris.* Fig. 2, anterior tarsus of the male. Fig. 3, anterior tarsus of the female. Fig. 4, labrum of another species of *Cicindela.* Fig. 5, mentum of the same; *a a*, labial palpi. Fig. 6, mandible. Fig. 7, maxilla; *a*, external maxillary palpi; *b*, internal maxillary palpi. Figs. 8, 9, 10, 11, and 12, wing-cases of five different species of *Cicindela*, to show the variation in the markings.

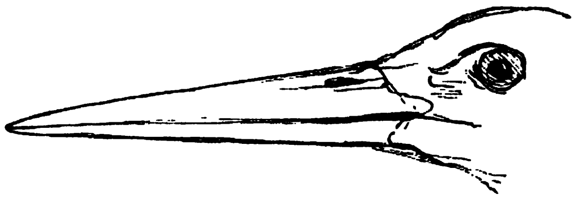
Four other British species of the genus *Cicindela* — *C. sylvatica*, *C. maritima*, *C. aprica*, and *C. sylvicola*, have white or cream-coloured spots in the same situations as in *C. campestris*, but they are joined together in pairs; the two towards the base of the wing-case form a curved dash which surrounds the shoulder; the one on the disc of the elytron and that at the margin nearest it are also joined, and form a bent fascia, and the two at the apex form a bent dash, which follows the outline of that part of the wing-case. This disposition of the markings, namely, a lunular spot at the shoulder, a bent fascia in the middle, and another lunular spot at the apex of the elytron, is that which is most commonly found in the species, and the most common colour is brownish-bronze; such is the colour of *C. maritima*, *C. riparia*, and *C. sylvicola;* the latter sometimes varies to a green hue.

In some exotic species of *Cicindela* the elytra are adorned with numerous spots; eleven is the greatest number we have found; of these, however, three or four are often obliterated, and the others are joined (two or three together) so as often to form three irregular-shaped oblong dashes or fasciæ.

In some instances the markings run one into the other, so that there is more white than ground-colour; and in one species, now before us, the wing-cases are entirely white. These markings vary but slightly in individuals of the same species.

The *Cicindelidæ*, in most arrangements of insects, form the first family of the *Coleoptera.*

CICONIA (Brisson), a genus of Birds belonging to the family *Ardeidæ*, and including the species popularly called Storks. The genus has the following characters:—Bill long, straight, subcylindrical, in form of an elongated cone, pointed, trenchant, butt (arête) rounded, of equal height with the head; lower mandible a little curved upwards. Nostrils slit longitudinally in the horny substance of the bill, placed near the base. Eyes surrounded with a naked space, which does not communicate with the bill; the face, the space round the eyes, or a part of the neck, often naked. Feet long; three toes forward, united by a membrane up to the first joint, the posterior toe articulated on the same level with the others; nails short, depressed, without dentilations. Wings moderate; the first quill shorter than the second, which is rather shorter than the third, fourth, and fifth, which are the longest. (Temminck.)



Bill of Stork.

M. Temminck observes that the Storks live in marshes, and feed principally on reptiles, frogs and their spawn, as well as fishes, small mammiferous animals, and young birds. They are, in all the countries of the world where they occur, a privileged race on account of their utility and of the havoc they make among noxious animals. Their migration takes place in great flocks: they are easily tamed. The moult is autumnal. The sexes do not differ. All the species make a clattering noise with their bills.

The species best known are the White Stork (*Ciconia alba*), and the Black Stork (*C. nigra*), both of which are British birds. We select the former as an example of that part of the genus which consists of the Storks properly so called.

The White or Common Stork is the Πελαργός of Aristotle and the Greeks; *Ciconia* of the Romans; Cicogna, Cicogna Bianca, and Zigognia of the Italians; Cicogne and Cigogne Blanche of the French; and Weisser Storch of the Germans.

C. alba (*Ardea Ciconia*, Montague), the White Stork, or Common Stork. It has the bill straight, smooth; naked skin of the cheeks very small, and not communicating with the bill. Plumage white. Head, neck, and all the parts of the body, pure white; scapulars and the wings black; bill and feet red; naked skin around the eyes black; iris brown. Length 3 feet 5 or 6 inches.

Young.—The tarnished black of the wings is tinged with brown in the young birds, and the bill of a reddish-black.

Common Stork (*Ciconia alba*).

Habits, Food, Reproduction, &c.—Assured by the kindness with which it is treated, in requital for its services in clearing the land of dead as well as living nuisances, the White Stork approaches the dwellings of man without fear. In Holland and Germany especially, the bird is treated as a welcome guest, and there, as indeed elsewhere, it annually returns to the nest which has cradled many generations, on the steeple, on the turret, on the false chimney that the Hollander has erected for its site, in the box, or on the platform which the German has placed for its use. The stump of a decayed tree is sometimes chosen by the bird, and the nest is made of sticks and twigs, on which are laid from three to five cream-coloured or yellowish-white eggs, about the size of those of a goose. The incubation continues for a month, at the expiration of which period the young are hatched, and carefully attended to by the parents until they are fully feathered and able to procure food for themselves. Frogs, lizards, snakes, and other reptiles, mice, moles, worms, insects, eels, the young of ducks and other waterfowl occasionally, and even partridges, according to M. Temminck, are devoured by these birds. In the continental towns domesticated Storks, which have been taken from the nest when young, may be often seen parading about the markets, where they are kept as scavengers to clear the place of the entrails of fish and other offal, which they do to the satisfaction of their employers.

Geographical Distribution.—The arrival of the Stork in Europe takes place in the spring. In Seville it is very common; but, according to the Prince of Canino, it is very rare and only an accidental visitor near Rome. Though so common in Holland, it very rarely arrives in Britain. The general drainage of our marshes may have something to do with this, but is hardly sufficient to account for so striking a difference in the migratory distribution of the bird, more especially as it proceeds to higher latitudes; for it regularly visits Sweden and the north of Russia, and breeds there. The winter is passed by the bird in the more genial climates of Asia, and in the northern part of Africa, Egypt especially. Those who have seen these birds in the act of migration, speak of their numbers as very large: thus Belon remarks, that the Storks are never seen in flocks except when they are in the air; and he relates how, being at Abydos in the month of August, a great flight of Storks came from the north, and when they reached the commencement of the Mediterranean Sea they there made many circuitous turns, and then dispersed into smaller companies. When Dr. Shaw was journeying over Mount Carmel he saw the annual migration of those which had quitted Egypt; and he states that each of the flocks was half a mile in breadth, and occupied three hours in passing over. They have been occasionally seen in considerable numbers in Great Britain, but the instances in which they have been killed are few.

Utility to man.—The utility of this bird to man in clearing away noxious animals and filth has given it a claim to protection, that has rendered it quite at its ease in his presence wherever that protection has been afforded.

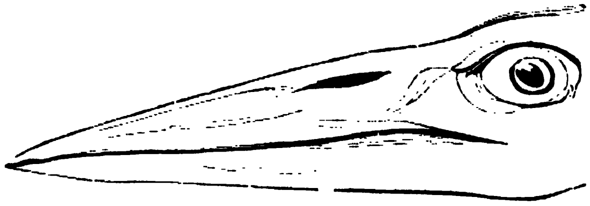
C. nigra (*Ardea nigra*), the Black Stork, Cigogne Noir of the French. Like the last this species is a migratory bird. It passes the winter in the southern parts of Europe, and in spring advances to high northern latitudes to spend the summer. Mr. Yarrell says that he can make out only four authentic instances in which this bird has been shot in England.

M. Temminck remarks that all those gigantic species of foreign Storks arranged by systematists under the name of *Mycteria*, have the same external characters with the European Storks, the same manners and the same habits, and he further refers to the fact that Illiger in his 'Prodromus' has given his opinion that the genera *Mycteria* and *Ciconia* ought to be united.

Mr. Selby, after giving the characters of the genus *Ciconia*, says, "My readers will observe that these generic characters are not applicable to all the species of the genus *Ciconia*, of Bechstein, Cuvier, Temminck, and Wagler, but only to that group of which *C. alba* may be considered the type. The larger species, namely, *C. Marabou*, *Argala*, *Mycteria*, &c., seem to me possessed of characters sufficiently distinct to warrant such a separation, a fact indeed admitted by the necessity under which these authors have found themselves of subdividing their genus into sections."

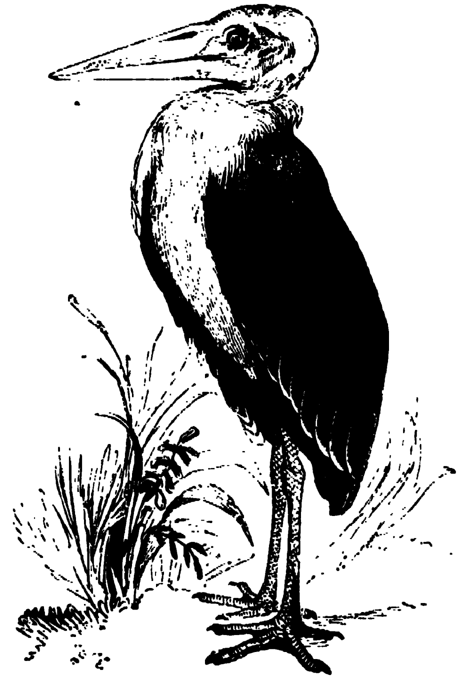
Of these, the three gigantic species of Stork remarkable for the comparative nakedness of the head and neck, a kind of pouch which hangs externally in front of the neck, and a sort of vesicular apparatus or portion of skin at the back of the neck which can be inflated by the bird, and the greater enlargement of the bill, deserve especial notice. These extraordinary and uncouth-looking birds are natives of Africa and the eastern parts of Asia, and have only been known to modern naturalists within the last fifty or sixty years.

Ives in his voyage to India (1773) made known a gigantic grallatorial bird, from which Dr. Latham described the Adjutant of the British residents at Calcutta (the Argala of the natives), with the name of the Gigantic Crane. At the same time he noticed the observations made by Smeathman, the African traveller, on the habits of a bird seen by the latter on the western coast of that quarter of the globe. Gmelin upon this information founded a species, *Ardea dubia*, and Latham, who had figured the bird, and related some additional particulars of its habits in the first supplement to his 'Synopsis' (1787), changed the name in his 'Index Ornithologicus' to *Ardea Argala*. Mr. Bennett, who adverts to these points, proceeds thus: "Mr. Marsden, in his 'History of Sumatra,' makes mention of a bird, called by the natives of that island Boorong-Cambing, or Boorong-Oolar, which was generally believed to be of the same species with the Adjutant of Bengal. Dr. Horsfield however, in a paper published in the 13th volume of the 'Linnæan Transactions,' separates a Javanese bird, which is probably the same with the Sumatran, as a distinct species. Subsequently M. Temminck, in his 'Planches Coloriées,' has shown that the African species differs in several essential particulars from that of the continent of India, and still more remarkably from that of Java and the neighbouring islands. By his figures of the three species, all taken from living specimens, he has so clearly determined their characters that it is scarcely possible they should ever again be confounded. In one point however he has himself given rise to a different kind of confusion, that of their nomenclature. They all furnish, in more or less perfection, the beautiful plumes, superior in estimation even to those of the ostrich, known by the name of Marabous, from their appellation in Senegal. But those of the Indian species being far superior to the others, M. Temminck has thought fit to transfer to that bird the name of *C. Marabou*, and to rob it of its native appellation, Argala, which he has bestowed upon the African. The consequence of this perversion of their native names has been such as might have been expected. In the late edition of his 'Règne Animal,' M. Cuvier quotes the *C. Marabou* of Temminck, with the characters of the Indian bird, as a native of Senegal; while he states the *C. Argala* of the same author, to which he attributes the characters of the African species, to be brought from India. Nothing could more strongly evince the necessity of restoring, as Mr. Vigors had previously done, in the Appendix to Major Denham's 'Travels in Africa,' the name of *Argala* to the Indian, and that of *Marabou* to the African species."



Bill of African Gigantic Stork (*Ciconia Marabou*).

C. Marabou, Vigors. M. Temminck has clearly pointed out the differences between this species and the Indian *Argala*. The African *Marabou* is less in size than the Indian *Argala*, the latter sometimes reaching six or even seven feet in height, while the former seldom exceeds five feet, even when the neck is elongated. The bill of the *Argala* is enlarged in the middle, the culmen of the upper mandible and the edges of the lower form a curved line from the base to the apex; in the *Marabou* the lines are straight and the bill is regularly conical; the nostrils of the Indian bird are ovate, those of the African species are oblong. The iris of the former approaches to pure white; that of the latter is dull-brown. The cervical or sternal pouch often hangs down more than a foot in the *Argala*; in the *Marabou* it is much shorter. The back and wings of the *Argala* are dull-black; in the *Marabou* there is a greenish tinge on the black of the back, with the exception of the larger wing-coverts and the secondaries, which are of a more decided black, edged more or less broadly and distinctly, according to the age of the individual, with pure white bands. In the young birds these last distinctions are imperceptible. In both species the bill is inclined to livid yellow in colour, and is more or less spotted with black towards the base, as is the head, which is dusky. When the bird is at rest the pouch as well as the neck are of a pale flesh-colour, but when it is excited they acquire a redder tinge. These parts are sparingly covered with a few scattered brownish hairs, most



African Gigantic Stork, or Crane (*Ciconia Marabou*).

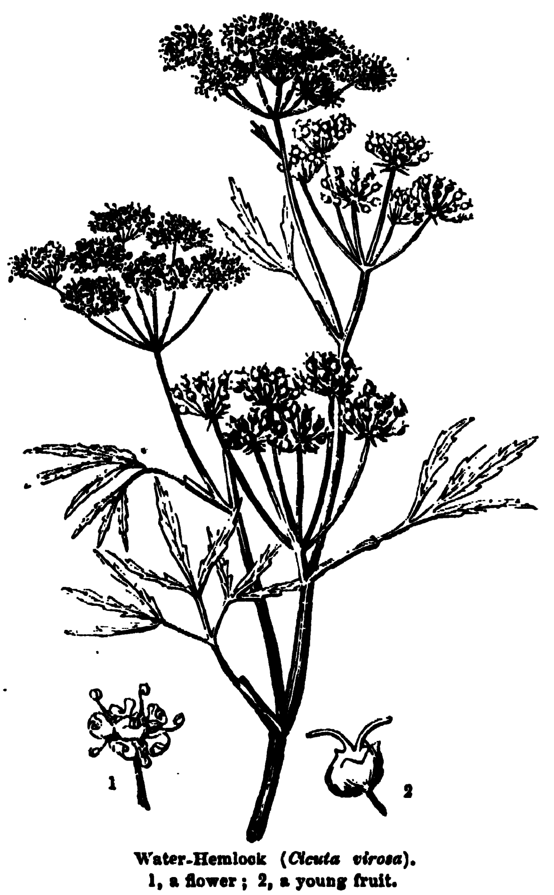
numerous in the young birds, and resembling down in the early stages of its growth. The tail is black; the under parts pure white, more especially the under tail coverts, which afford the beautiful plumes. These are sometimes of a grayish slate-colour in the Indian species; but the white of the African feathers is not so clear and brilliant as that of the Indian plumes, to which a decided and just preference is given. The natural colour of the legs is dusky black, but in living birds these limbs are generally whitened by the dust shaken out of the plumage and other excrement.

Geographical Distribution of the Marabou.—Nearly the whole of Tropical Africa to the Cape of Good Hope, where it is not common. (Temminck.) Banks of the Nile. (Rüppell.) Neighbourhood of the large towns of the interior. (Denham.) Western coast. (Smeathman.)

Habits, Food, &c.—Nearly resembling those of the White Stork, like which it is privileged, on account of its utility as a scavenger in freeing the villages and towns of offensive substances, like its Indian congener. Its omnivorous voracity is well described by Denham. Where carrion and filth are scarce, reptiles, small birds, and small quadrupeds fall victims to its appetite. These are usually swallowed entire. Smeathman gave to Dr. Latham an anecdote of a domesticated individual which roosted very high among the silk-cotton trees, and would descry the servants bringing the dishes to the dinner-table, from a distance of two or three miles from its perch. It stood behind its master's chair waiting to be fed, and occasionally helped itself, notwithstanding the guardianship of the servants who carried switches to prevent its snatching the meat, which it nevertheless sometimes contrived to do: in this way it had been known to swallow a boiled fowl at a single mouthful. Besides the pouch, the skin at the back of the neck can be inflated so as to have somewhat the appearance of a counterpoise to the former. When the sun is shining upon the bird we have observed this latter pouch, if pouch it may be called, very prominent, apparently from the rarefaction of the air. The bird flies high and roosts high, probably for the purpose of taking in a large area of observation, to enable it to perceive those objects on which it feeds. May not these pouches assist, balloon-like, in supporting or balancing the great head and bill? Living specimens of the White and Black Stork, the Marabou, Jabiru, and American Maguari are now in the Gardens of the Zoological Society, Regent's Park.

CICU'TA, a genus of plants belonging to the natural order *Umbelliferæ*, the sub-order *Orthospermeæ*, and the tribe *Ammineæ*. It has a calyx of 5 leaf-like teeth; the petals obcordate, with an inflexed point; the fruit subdidymous; the carpels with 5 equal broad flattened ridges, the lateral marginal; the vittæ solitary.

C. virosa, the Water-Hemlock, is a wild poisonous plant found occasionally by the sides of ditches and ponds. It is a perennial plant, with a large fleshy white root covered externally with fibres, and divided internally into several low chambers filled with a milky or yellowish juice. The stem is erect, hollow, cylindrical, striated, and 2 or 3 feet high. The leaves, especially the lower ones, are decomposed or thrice-pinnated; the leaflets are narrow, lanceolate, deeply and irregularly toothed. The umbels are usually destitute of involucre, or if they have one it is nothing but a single linear bract; the partial umbels have several such bracts. The flowers, which are white, have the ordinary umbelliferous structure. They are succeeded by globular double fruit, crowned by the style and five teeth of the calyx, and showing on each of their convex faces five salient simple angles. Its medicinal properties are similar to those of common Hemlock [Conium], but more energetic. Its roots have been mistaken by children and country folks for parsnips, and have been eaten with fatal consequences.



Water-Hemlock (*Cicuta virosa*).
1, a flower; 2, a young fruit.

CIDARIS, a genus of Star-Fishes belonging to the family *Echinidæ*. It has a globose body; mouth and anus nearly equal; ambulacra continuous from mouth to anus, which are both central, the former below, the latter above; the spiniferous tubercles perforate, the spines of several forms.

C. papillata, the Piper, is a British species, and is the most elegant of our native sea-urchins, but at the same time the rarest. It is found off the island of Zetland. It is always found in company with the Tusk (*Gadus brosmus*), a fish that is never found but on rocky ground. It is covered with two sorts of spines; one set long, the other short. The longer ones are ordinarily an inch or an inch and a half in length. In Zetland it is said they have been caught with the spines a foot long. (Forbes, *British Star-Fishes*.)

CI'LIA, in Anatomy, small moving organs found on the surface of the tissues of most animals, resembling hairs, and requiring the use of the microscope to be distinctly observed. They are mostly found on tissues which are in contact with water, or which produce fluid secretions. They are constantly in a state of active movement, and impart to the fluid with which they are in contact the same motion. This is called vibratory or ciliary motion. The best time for observing Cilia with the microscope is when their movement begins to slacken. Their figure is generally that of slender conical or sometimes flattened filaments, which are broad at the base or root and gradually taper to the point. Their size differs greatly on different parts of the same animal. "The largest I have measured," says Dr. Sharpey, "are those on the point or angle of the branchial laminæ in the *Buccinum undatum*; they are at least $\frac{1}{500}$ of an inch long. I have not attempted to determine the exact size of the smallest, but Purkinje and Valentin state it at 0.000075 of an inch, while they make the largest they have met with only 0·000908 of an inch, which is considerably less than I have found them; but they had no opportunity of examining marine animals, in which generally speaking the largest cilia are met with. In the sea-mussel the darker coloured cilia are about $\frac{1}{1000}$ of an inch long, the others considerably less." The substance of the Cilia is for the most part transparent and colourless, in some however a slight colouring may be observed. They assume also various forms, and Ehrenberg has described compound Cilia in the *Infusoria*. In the Ciliograde *Medusæ* the Cilia consist of rows of broad flattened organs, each of which is made up of several simple filaments joined together by a connecting membrane throughout their whole length. In most cases the Cilia are arranged in regular order. On the gills of the mussel they are placed in straight rows; in many of the *Infusoria* they are arranged in circles or spiral lines. In some instances they are erect, but in others they are placed at right angles to the surface on which they are seated.

The movement of the Cilia is not very rapid, and may be easily observed with a lens of $\frac{1}{35}$ inch focus. Their most obvious movement is of a fanning lashing kind, the Cilium being bent in one direction and returning to it again. In addition to this movement Professor Quekett detected another in the Cilia of the gill-rays of the common mussel. This consists of a slight movement of the Cilia on themselves, each Cilium turning on its own axis through the space of a quarter of a circle, with a movement like that of the feathering of an oar in rowing. This observation of Mr. Quekett's is of importance, as it explains how it is that the Cilia are capable of propelling bodies over their points which could not be effected by the first-observed up and down movement. When the surface of an organ is examined on which are seated a large number of Cilia, a wave-like motion in the whole is observed, which arises from the regularity with which each Cilium is affected with the movement.

The Cilia were first observed as present on the external surface of the bodies of infusory animalcules. Leeuwenhoek seems to be one of the earliest observers who described the presence of the Cilia in animalcules. In his 'Continuatio Arcanorum Naturæ' he describes in many places the nature of the Cilia in the common polygastric animalcules as well as in the wheel-animalcules. He also pointed out the probable use of these organs, for he says, "Moreover it is necessary that these animals, and in general all such as are fixed and cannot change their place, should be provided with an apparatus for stirring up motion in the water, by which motion they obtain any matters that float in the water for their nourishment and growth, and for covering their bodies." Since the period that Leeuwenhoek wrote they have been observed in almost every species of *Infusoria*, and seem to be the active organs by means of which these animals move from place to place and carry their food into their stomachs. In the Polypes they are found in great numbers covering the surface of the tentacula by which these animals obtain their food. Although they have not been observed on the full-grown Sponges they have been described by Dr. Grant as existing upon the ova of these animals before they become fixed. Though not abundant in the *Acalephæ*, they have been seen by Dr. Grant and others in the *Beröe pileus* and other *Medusæ*. Dr. Sharpey has observed them in the various forms of the *Echinodermata*, and also in the *Annelida*. In the *Mollusca* they are very abundant, and one of the best means of examining these organs is afforded by the common mussel. Till within a recent period it was supposed that Cilia were confined to the Invertebrate classes of animals, or at least the observation of their existence to any extent in the *Vertebrata* was very limited. One of the earliest observations of their presence in Vertebrate animals was by Steinbuck, a German anatomist, who found them upon the gills of the Salamander. Within the last few years Purkinje and Valentin have devoted much attention to the subject, and have found that Cilia exist very generally on the moist surfaces of the membranes of all the higher animals. The systems of organs on the surface of which Cilia have been detected are as follows:—

1. The Surface of the Body.—In this situation Cilia have been detected in the *Infusoria*, *Polypi*, *Medusæ*, *Actinia*, *Echinodermata*, and in the larvæ of the Batrachian Reptiles.

2. The Respiratory System.—Cilia have been detected in the lining membrane of the air-passages of reptiles, birds, and *Mammalia*, in the gills of the larvæ of the *Batrachia*, and on those of the *Mollusca* and *Annelida*. Those on the external surface of the *Infusoria*, Polypes, and *Medusæ* must also be regarded as belonging to the respiratory system.

3. Alimentary System.—They are found in the mouth, throat, and gullet of Reptiles, in the entire alimentary canal of *Mollusca*, in the stomach of the *Asterias*, &c.

4. Reproductive System.—Ciliary movements have been observed in the mucous membrane of the Fallopian tubes, in the uterus and vagina of *Mammalia*, and in the oviduct of Birds and Reptiles. A peculiar ciliary movement has been observed in the embryo of many animals. This movement occurs while the embryo is in the ovum, the Cilia producing a current in a certain direction along its surface, or causing the whole embryo to move in an opposite direction. In many instances when the embryo has escaped the egg it moves about by means of Cilia in the same way as occurs in the naked gemmules of the Sponge.

There can be little doubt that the functions performed by the Cilia in these various parts of the body of animals are important; at the same time their absence in a great number of cases, in organs which perform the same functions as those which possess them, must lead to some hesitation before pronouncing a decided opinion with regard to their use. Where they are situated on the external surface of the bodies of animals they seem to be the active organs of movement. Where respiration is carried on by means of the external surface, as in the *Infusoria* and *Polypifera*, the Cilia assist this process by removing the used water and bringing fresh currents to the surface containing the matter to be oxygenated. They may undoubtedly perform the same office when seated on internal respiratory membranes. On the surface of the reproductive organs of the higher animals they may also assist in bringing the unimpregnated ovum in contact with the fertilising cells of the male fluid. The movement in the embryo has probably the same object in view as that on the respiratory membranes, the bringing the surface in contact with currents of oxygenated water.

In coming to the conclusion that the motions of fluids on the surfaces of membranes are produced by Cilia where these organs exist, Dr. Sharpey observes, "The currents cease when the motion of the cilia stops, they are strong and rapid when it is brisk, and feeble when it languishes; and though there are modifying circumstances or perhaps exceptions, yet in general the magnitude and velocity of the current seem to be proportioned to the size and activity of the cilia. It is true that while doubts remained as to the existence of cilia in several well-marked instances where the water unequivocally received its motion from the surface over which it flowed, and independently of any visible contractions of the animal tissue, there was always considerable room to doubt, whether, even in the cases where cilia were manifest, the effect of these organs was wholly mechanical, and whether the motion of the water was not rather due to some peculiar impulsive power in the tissue differing from mechanical action. But more extended observation has almost wholly removed these exceptions, while it has considerably increased the number of conforming instances, insomuch that there seems at present no necessity for having recourse to any other explanation of the motion of the fluids than that it is produced by the action of the cilia, and that their action is the result of muscular contractility, a known property of animal tissues."

There are however some remarkable exceptional cases. Currents are observed in the Sponge, in the stem and branches of the *Sertulariæ*, but no Cilia. There are also a number of remarkable cases of the movements of fluids in cells in the vegetable kingdom, which cannot be ascribed to the existence of Cilia, as those seen in the cells of *Chara*, *Valisneria*, the hairs of *Tradescantia*, &c.

When first discovered the Cilia were supposed to be confined to the organs of animal bodies. In 1843 Meyer and Thuret announced that they had discovered Cilia on the spores of several species of *Confervæ*. They were subsequently discovered on the surface of several species of unicellular plants, as also on the spermatozoids, which occur in the Ferns and many of the lower forms of *Cryptogamia*.

For further information consult the article 'Cilia,' by Dr. Sharpey, in the 'Cyclopædia of Anatomy and Physiology,' to which we are much indebted in drawing up this article; also the paper of Purkinje and Valentin, entitled 'Commentatio Physiologica de Phænomeno Motus Vibratorii continui,' &c., translated in the 'Dublin Journal of Medical and Chemical Science' for May, 1835, and in 'Edinburgh New Philosophical Journal,' vol. xix.; also 'On Unicellular Plants and Animals,' 'Microscopical Journal,' vol. i.

CILIATA. [MOTELLA.]

CILICÆA. [ISOPODA.]

CILIOGRADA. [ACALEPHÆ.]

CIMBEX, a genus of Hymenopterous Insects of the section *Terebrantia*, sub-section *Securifera*, and family *Tenthredinidæ*.

The genus *Cimbex*, as it formerly stood, has been subdivided (principally by Dr. Leach) into the following sub-genera: *Cimbex*, *Perga*, *Syzygonia*, *Trichiosoma*, *Clavellaria*, *Zarea*, *Abia*, and *Amasis*. All these sub-genera have the antennæ short, and terminated by thickened joints, which are nearly of an oval form; the third joint of the antennæ is long, forming a knob: the superior wings have two marginal and three sub-marginal cells.

The antennæ of these insects generally present six distinct joints, of which the two basal joints are very short, and almost concealed by the hair on the head; the third is long, the fourth and fifth are of moderate length, and the sixth is elongate (or moderate), rounded at the apex, and tapers more or less towards the base; this last joint is, however, evidently composed of two or three joints consolidated. All the joints of the tarsi have a membranous pad attached to their under side, and protruding from their apex.

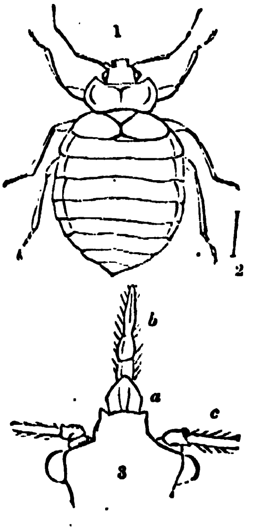
The genus *Cimbex*, as now restricted, may be known by the following characters:—Body slightly hairy; abdomen with the basal segment emarginate above (that is, it appears as if a semicircular piece had been removed); the space thus left unprotected by the horny covering filled up with a membrane. Thighs of the four posterior legs of the males very thick, those of the females moderate. Tarsi of the males with a tooth-like projection on the under side of the basal segment.

This genus includes the largest species of the family *Tenthredinidæ*. *C. Griffinii* is about an inch in length, and when the wings are expanded its width is about one inch and three quarters. It is of a reddish-brown colour; the abdomen is yellow, and more or less clouded with brown towards the base; the antennæ and tarsi are yellow, the former is brighter towards the apex.

The larva, we have been informed, feeds upon the sallow, and is not uncommon in the neighbourhood of Cambridge. Mr. Stephens enumerates eight British species of this genus, some of which however, it is thought, will eventually prove to be mere varieties.

CIMEX. [BUG; CIMICIDÆ.]

CIMICIDÆ, a family of Hemipterous Insects, the species of which may be distinguished by their having the rostrum short, and consisting of two or three joints only; the labrum also short, and without striæ; the eyes are moderate; the body is generally very much depressed. The principal genera are *Cimex*, *Aneurus*, *Aradus*, *Agramma*, *Tingis*, and *Dictyonota*, all of which are found in England. The genus *Cimex* is distinguished principally by the extreme slenderness of the two terminal joints of the antennæ, which are not thicker than a hair. The body is very much depressed: the thorax is transverse; antennæ 4-jointed; basal joint very short, second long, the third of about equal length, the fourth rather shorter. Labrum rather long, somewhat pointed, and, when the proboscis is not in use, recurved under the head; proboscis 3-jointed, and, when at rest, lies along the under side of the thorax, its apex being between the two fore legs at their base.



1, Bed-Bug (*Cimex lectularius*) magnified; 2, natural length of the same; 3, head of the same, highly magnified; *a*, the labrum; *b*, the proboscis; *c*, base of the antennæ.

The most common species is the *Cimex lectularius*, the Bed-Bug. [BUG.]

CIMICI'FUGA (*cimex*, a bug, and *fugo*, to drive away), a genus of Plants belonging to the natural order *Ranunculaceæ*. The calyx is composed of four deciduous sepals; corolla of four petals; styles one to fifteen; the carpels dry, dehiscent, many-seeded. The species are perennial herbs, with divided leaves, and racemes of whitish flowers; the roots act as drastic purgatives and are poisonous.

C. fœtida, Stinking Bug-Wort, has four almost sessile and very villous ovaries; the racemes panicled; the leaves terminate or biternate; the leaflets ovate-oblong, deeply-toothed. It is a native of the Carpathian Mountains, Dauria, Eastern Siberia, and the north-west coast of America. It is a very fetid plant, and is used in Siberia for driving away bugs and fleas, just as tansy and wormwood are used in this country.

C. serpentaria, Black Snake-Root or Bug-Wort, has compound very long racemes; the leaves triternate, with serrated or rather cut leaflets. It is a native of North America, from Canada to Florida. It has white flowers, and resembles the species of *Actæa*, to which genus it was formerly referred under the name of *Actæa racemosa*. Like many other plants possessing active properties, it has a reputation in America for healing the bites of snakes and preventing their poisonous effects on the system. There is one species, *C. Japonica*, a native of Japan; the rest are American plants. They are easily cultivated, preferring a moist shady situation, and may be propagated by dividing the roots, or by seeds.

(Don, *Gardener's Dictionary.*)

CIMOLITE, a hydrous silicate of alumina found in the Island of Cimola. It occurs in amorphous earthy masses, the structure of which is rather slaty. Colour grayish-white. Fracture earthy, uneven. It is soft and opaque, and its specific gravity is 2·0. It is used for the same purposes as Fuller's Earth. It is allied to Halloysite. [HALLOYSITE.]

CI'NCHONA, a genus of Monopetalous Exogenous Plants, the different species of which have a great reputation in medicine. It constitutes the type of the natural order *Cinchonaceæ*. It is known by the following characters:—Tube of the calyx top-shaped, with a permanent 5-cleft limb. Corolla with a taper tube, and a 5-parted limb, which is valvate in æstivation. Filaments short, inserted into the middle of the tube, within which the linear anthers are altogether inclosed. Stigma 2-cleft, a little clavate. Capsule ovate or oblong, slightly marked on each side by a furrow, 2-celled, crowned by the calyx, dividing through its dissepiments into two halves. Placenta long. Seeds numerous, erect, imbricated upwards, compressed, with a broad membranous winged border; albumen fleshy. Trees or shrubs, with a bitter aromatic astringent bark. Leaves on short stalks, with flat edges. Stipules ovate or oblong, leafy, separate, deciduous. Flowers in terminal panicled corymbs, white, or of a rosy-purple colour.

By whom the important properties of the various species of this genus were first made known to Europeans is unrecorded; for it is not worth repeating the fables that have been invented upon the subject. The native Peruvians, who call the trees Kina, or Kinken, attach no febrifugal importance to the bark, but are said even to have a prejudice against its employment. Its introduction to Europe took place through the Spaniards in the year 1640, and it is pretended that a certain countess Chinchon, vice-queen of Peru, having experienced the good effects of the bark as a febrifuge, it gained the name of Pulvis Comitissæ, and under that name, or as Pulvis Jesuiticus, was vended by the Jesuits, who derived a considerable part of their wealth from its trade. Humboldt regards a tradition still current in Loxa as a more probable explanation of the discovery of the properties of *Cinchona*. It is said that the Jesuit missionaries there had endeavoured, according to the custom of the country, to distinguish the different kinds of trees by chewing their bark, and that this had led them to observe the remarkable bitterness of *Cinchona*. Those who were medical among them were thus led to try an infusion of the bark in tertian agues, which are very common at Loxa, and thus the discovery of its power was made. Little was known of the tree producing this substance till the voyage of La Condamine, who, in 1738, first printed a detailed account of Quinquina, as it was then called. Since that time the attention of botanists has been constantly directed to the subject, and a good deal of information has upon the whole been collected; the general facts connected with the habitation, geographical range, modes of preparation, and botanical distinctions of the species have been ably stated by Humboldt, Ruiz and Pavon, Fée, De Candolle, Lambert, Pöppig, and Lindley, and will form the basis of the succeeding short account; but in all the minor details regarding the barks themselves, and the species that furnish them, Europeans are still much in the dark.

To this genus botanists have from time to time referred plants which, upon a more careful examination, have been ascertained not to belong to it; West Indian, Brazilian, and even East Indian Cinchonas, thus have found a place in books, but they are really referrible to other genera. Circumscribed within the limits of the preceding character, *Cinchona* will be found a mountainous genus confined to the Cordilleras, between La Paz, in about 22° S. lat., and Santa Martha, near 10° N. lat.; a line having these northern and southern limits, and bounded by the most eastern part of the Cordilleras on the one hand and the Pacific on the other, will very nearly define the corner of the globe inhabited by true Cinchonas. Within these limits they occur on the plains, but chiefly on mountain sides as far as 10,000 feet of elevation above the sea, the principal zone being at from 1800 to 6600 feet of elevation. In these places the mean temperature is estimated by Humboldt at from 17° centigrade, or 62·6° Fahrenheit, to 12° centigrade, or 53·6° Fahrenheit.

The manner of collecting the Huanuco Bark of commerce is thus described by Pöppig ('Companion to the Botanical Magazine,' vol. i. p. 249). "In the month of April the preparations for an expedition commence; and in May the people start for the forest, whence the last green bales are transmitted home in November. They fell the trees close to the root, sparing those trunks which appear too young (palos verdes), as, till they have attained maturity, the bark is of no value. The next process is to divide (trozar) the stems into pieces of uniform length, rejecting only the very smallest branches. With a peculiar kind of knife, made for the purpose, the bark is cut lengthwise, and a certain degree of practice is necessary to perform this operation properly so as to remove the rind without injuring the wood or severing any of the fibres. With the same instrument they take off the stripes (longos) of the bark as broad as possible; but this however is not done for three or four days after the tree is felled, as before that time the moisture that exists between the cuticle and the wood would prevent the bark from severing into such large pieces as fetch the highest price. A worse consequence ensues from stripping the stems too quickly, as then the thin grey or blackish epidermis shivers off; and from the presence of this outward rind, covered with many cryptogamia, the value of the bark in the European market is mainly estimated. The English purchasers in particular hold the notion that the bark is most powerful according as its epidermis is covered with spots.

"On the celerity with which the article is dried depends the price which it commands; but there are few instances where prejudice is so powerful as in the trade of the Cinchonas. In the dense forests it is impossible to perform this operation properly, and therefore the bundles of green bark are dispatched with all speed to the nearest inhabited place, where the person appointed to take the charge of them is stationed. Without any preparation they are laid in a spot exposed to the full action of the sun, the greatest care being requisite to protect them from wet, as even a few hours' dew falling on the half-dried bark will give to the cinnamon-brown interior of the finest sort a blackish appearance, and lessen its value about one-half. The quickness of the drying and the general excellence of the article are indicated by the pieces being rolled up into several spiral windings, which form so solid a cylinder as to exhibit no cavity (canuto) within; but such portions are rarely seen unfractured in Europe. The Cinchona barks are no less sensible of atmospheric moisture than the Coca, which I formerly described, so that the collectors always hasten to send them to the dry climate of the Andes, or the principal towns. An unavoidable loss however hence accrues: however perfectly the bark may have been dried in the woody region, it still loses, in three or four days after its arrival in Huanuco, 12 to 15 per cent. on its weight. The packages are made up into bales of four or five arrobas each, and with the greatest possible care, in order that the beautiful canes of two feet long, into which the bark was coiled on the Montaña, may not be broken in the carriage. Trailing plants (bejucos) are used to tie up the bundles, and when they arrive in Lima they are undone, and sorted into lengths of different pieces previously to dispatching them in chests to Europe. The trade in Huanuco Bark was very brisk twenty years ago at Lima, and the article went to the Spanish market under the name of *Cascarilla rosea*, without being confounded with the *Cortex Chinæ ruber*, as it is called by us. The barks from the districts of the Lower Huallaga, of Huambo and Chachapoyas, &c., are, on the other hand, very little prized in Cadiz, and called *Cascarilla arollada*."

Books and memoirs without end have been written to determine the different species of *Cinchona* that yield the barks of commerce, but with very little result. There are difficulties in the way of this which persons unacquainted with the bark trade can hardly estimate. For example, the bark of the same species may be weak and valueless in warm lowland districts, and of the greatest price in alpine or mountainous regions. The bark of the low country about S. Jaen de Bracamorros has uniformly proved worthless, although the same species which grow there afford a fair bark at Mayobamba, Chachapoyas, and Lamas in the mountains; and others which at Maynas are perfectly inert, are energetic enough upon the sides of the mountains. It is related by Pöppig that, in ignorance of this, many speculating merchants have been ruined by the purchase of the bad lowland bark of Peru. The rule is, that the best bark always comes from mountain tops, from single trees growing in the coldest and most elevated spots. Some of the finest kinds are procured near the mountain villages of Cayambe and Pillao, and from the mountains of Panataguas and Pampayaco.

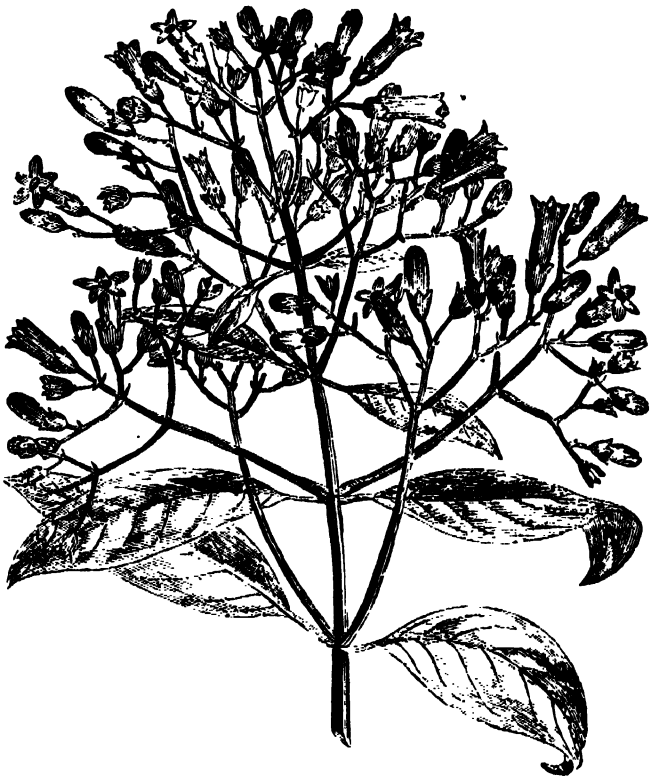
To pretend to reduce to their botanical species, in the existing state of knowledge of Cinchona barks, all the varieties that are known in shops or in commerce, would be a vain and hopeless task. Nothing can well be more startling than the discrepancies that exist upon the subject in books and collections; every collector, every writer, has his own set of specimens and opinions, and there is no possibility of reconciling them. There is not a chest of bark which, although called of one sort, has not probably been furnished by many different species; and there is much reason to believe that many of the best known sorts of barks of the shops are in reality furnished by the same species under different circumstances. Fée asserts that gray Quinquina passes into yellow by shades that cannot be distinguished; that yellow approaches the red both in colour and flavour; and that nobody knows to this day with any certainty the origin of even the barks of Loxa, Lima, Huanuco, or Carthagena. Pöppig, who has so long lived in the Cinchona countries, seems to be of the same opinion, notwithstanding the details he has given respecting certain species—details of which we have availed ourselves in the following observations. In particular, with reference to this subject, to which a vast deal more importance is attached than it deserves, when speaking of the Huanuco Bark of commerce, Pöppig's remarks are highly deserving of attention. He observes that as to the various species of trees that produce bark, and the different quality of the article itself, much prejudice exists. Without cause one species is rejected, and another prized for its imaginary qualities; and the same species is unmeaningly divided by the bark-collectors into several, upon no known or intelligible principle. *Cinchona glandulifera* has three names, although scarcely the least trace even of varieties can be detected upon the closest botanical examination.

It is doubtful whether the species of any genus of plants are more variable in their appearance than those of *Cinchona;* and hence those who have been acquainted with them from dried specimens only, or who have not been aware of their tendency to vary, have multiplied the species far beyond their true number, and an inextricable confusion would have been the result in any genus less constantly before the eyes of the botanist. Thus the authors of the 'Flora Peruviana' in that work added thirteen supposed new species, and introduced many more into their Herbarium; Mutis, on the other hand, who had ample means of studying Cinchonas in New Granada, declares that he was acquainted with seven only. Zea asserts that all the efficacious species of the 'Flora Peruviana' are reducible to four. Fée admits eighteen certain species; and De Candolle reduces the number to fifteen, although he introduces two species unknown to Fée. Humboldt states that he has himself seen *C. pubescens*, the yellow bark, with ovate-oblong, ovate-lanceolate, and ovate-cordate leaves on the same plant; he adds, that some species, such as *C. macrocarpa*, have either leaves entirely smooth or downy on each side, and that even *C. Condaminea* has extremely different leaves, according to the elevation at which it grows. These statements alone are sufficient to show how much caution is required in distinguishing species in this genus; but to this it is necessary to add, that there is too much reason to suspect that the authors of the 'Flora Peruviana,' in creating spurious species, were influenced by a wish to please the Spanish court, by appearing to prove that the barks of Peru, from which the Spaniards exclusively derived so large a revenue, were altogether different from those of New Granada, which other nations could easily procure direct from Carthagena. Humboldt adds, that mercantile cunning with reference to this subject was carried so far, that at the royal command a quantity of the best orange-coloured Cinchona bark from New Granada, which Mutis had caused to be picked at the expense of the king, was burned, as a decidedly inefficacious remedy, at a time when all the Spanish field-hospitals were in the greatest want of this indispensable product of South America. It should however be observed that some of Ruiz and Pavon's species have been restored by a recent writer upon the authority of dried specimens; but it appears to us safer in such a case as this to take the opinion of a man like Humboldt, who studied Cinchonas in their native forests, than that of a botanist who can be acquainted with them only from Herbaria.

In the following enumeration of the species we take De Candolle as our guide in the systematic distinctions of the species, and Humboldt and Pöppig principally for the practical observations upon them. After every specific name we have added the synonymous names that occur in books, for the information of those of our readers who may possess Materia Medica works whose nomenclature is different from that of De Candolle.

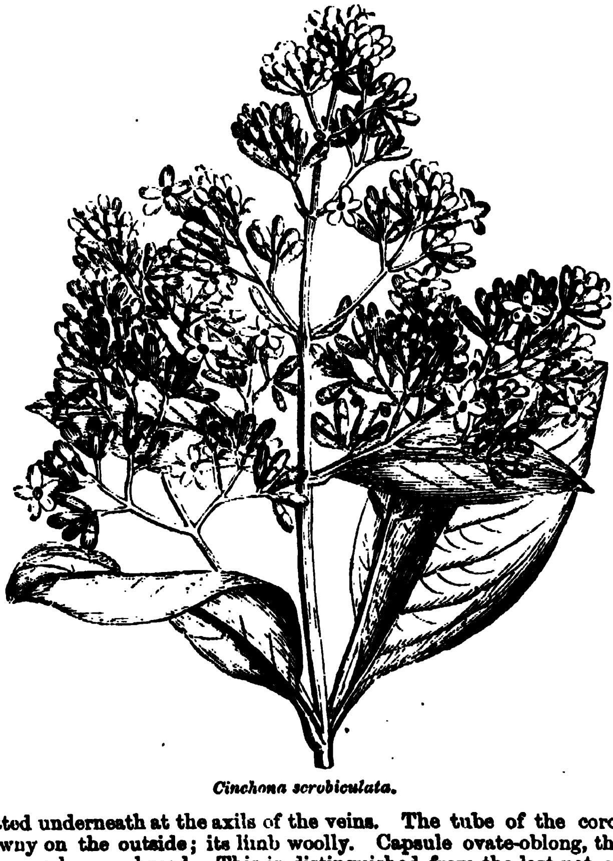
* Corollas downy on the outside or silky.

1. *C. Condaminea.* Leaves oblong, tapering to each end, smooth and shining, pitted on the under surface at the axils of the veins. Limb of the corolla woolly. Capsules ovate, twice as long as broad. This is the *C. officinalis*, Linn. Humboldt states this to be the fine Uritucinga Bark originally seen by La Condamine. It is one of the sorts imported in quantity to Europe, and is said to furnish the pale bark of the English apothecaries. It is readily known, notwithstanding the variable figure of its leaves, by their having at the axils of their veins on the under side little pits not bordered with hairs, and secreting a transparent bitter fluid matter. Grows wild near Loxa, in the mountains of Cajanuma, Uritucinga, Boqueron, Villonaco, and Monje. It also occurs near Guancabamba and Ayavaca in Peru. It is always found among micaceous schist, at elevations of from 5400 to 7200 feet; and, according to Humboldt, requires a milder climate than the *C. lancifolia* of Santa Fé. The temperature of the regions which it inhabits is about that of the Canary Islands. This is the *C. lancifolia* of the 'London Phamacopœia' of 1836, and is now recognised as yielding the pale bark (*Cinchona pallida*) of the London College of Physicians.



Cinchona Condaminea.

2. *C. scrobiculata* (*C. micrantha*, 'Fl. Peruv.,' Ruiz and Pavon). Leaves oval, acute at each end, smooth, shining on the upper side, pitted underneath at the axils of the veins. The tube of the corolla downy on the outside; its limb woolly. Capsule ovate-oblong, three times as long as broad. This is distinguished from the last not only



Cinchona scrobiculata.

by the form of its leaves, which never taper to the point, but also by the pits at the under side of the leaves being bordered with inflected hairs; in *C. Condaminea* they are quite hairless. It is also allied to *C. rosea*, but that species has a smooth corolla and glandless leaves. In the quality of its bark it is not distinguishable from *C. Condaminea*. Immense forests of this species exist in the province of S. Jaen de Bracamorros. It is the commonest of all the Quinas in that part of Peru, and the most esteemed; in commerce it has the name of Quina Fina. Dr. Lindley says this species is the origin of the Seloa, or Gray Cinchona of English commerce.

3. *C. lancifolia* (*C. angustifolia*, Pavon; *C. Tunita*, Lopez). Leaves obovate-lanceolate, very smooth on each side, without glands; panicle large, brachiate; corolla silky on the outside; capsules oblong, smoothish, five times as long as broad. Next to *C. Condaminea* this is accounted the most efficacious of all the species. It furnishes the orange-coloured bark, or the Quina Naranjanda of Santa Fé de Bogota, and is obviously different from the two former species in its leaves being destitute of glands. Humboldt states that it prefers an inclement climate, on mountainous declivities from 4000 to 9000 feet high, where the mean temperature is about that of Rome. In the alpine forests of the upper limits of the zone inhabited by this species the thermometer falls for hours as low as the freezing point. The plants are more rare than those of *C. pubescens* and *C. magnifolia*, always growing singly, and not increasing readily by the root. A kind of bark, bearing a high reputation at Cadiz, and called Calisaya, is referred to this species. It derives its name from the province where it grows, which is situated in the most southern part of Peru, in La Paz.

Another variety of this, according to Humboldt, a distinct species according to others, the *Cinchona nitida* of the 'Flora Peruviana,' is found only upon the coldest parts of the mountains of Peru, where it becomes a tree with a stem scarcely eight feet high. Its flowers are bright red, covered inside with a white down, and do not appear till May. Its bark, the Cascarilla Hoja de Oliva, although of the finest quality, is never seen in commerce.

4. *C. pubescens* (*C. cordifolia; C. ovata*, Ruiz and Pavon; *C. pallescens*, Ruiz; *C. hirsuta*, Ruiz and Pavon). Leaves ovate, very seldom sub-cordate, leathery, downy or nearly smooth on the upper side, tomentose on the under side; panicle brachiate; corolla downy outside, the limb hairy inside; capsules ovate, oblong, ribbed externally, three times as long as broad. A most variable plant, yielding what is called Yellow Bark. It is found in the republic of New Granada, in 4° N. lat., at heights between 5400 and 8650 feet; it has the name of Quina Amarilla.

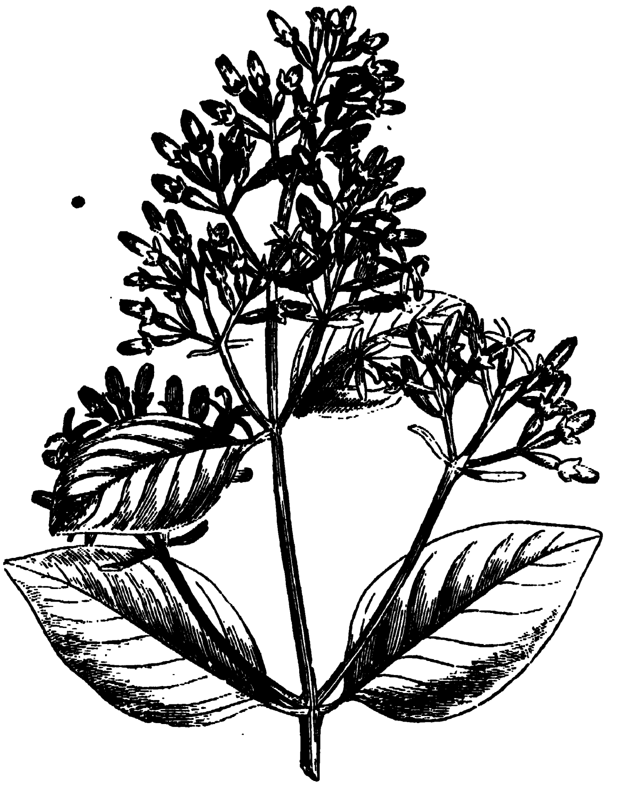
5. *C. purpurea*. Leaves broadly oval, somewhat wedge-shaped at the base, shortly cuspidate at the point, on the upper side smooth, on the under rather downy upon the principal veins; panicle large, brachiate; flowers somewhat corymbose; corolla slightly downy externally, its limb hairy inside; capsules cylindrical, becoming ovate-oblong, with longitudinal ribs, four times as long as broad. A native of the Peruvian Andes, in the coldest and deepest parts of the forests, about Chinchao, Pati, and elsewhere. It is also apparently one of the wild roots of Santa Fé de Bogota.

The very considerable size of the trees of this species, and its large membranous leaves, covered on the under side with prominent violet-coloured veins, are said by Pöppig to mark it readily. The bark, called Cascarilla Boba Colorada, is not in much esteem; but as it is readily collected it can be sold at a low price, and is used for adulterating other sorts. According to Reichel it is undoubtedly the Huamala Bark of trade. Dr. Lindley regards this and the foregoing species as identical.

6. *C. macrocalyx*. Leaves ovate, roundish, hardly acute, quite smooth on both sides; their principal veins close together; panicles corymbose; corolla slightly downy externally, with the lobes hairy on the upper side; limb of the calyx smooth, bell-shaped, acutely 5-toothed. A species distinguished by De Candolle by the above characters, but only known to him from specimens. It is found on the mountains of Peru. Nothing is known of its sensible properties.

7. *C. Humboldtiana* (*C. ovalifolia*, Bonpland). Leaves oval, rather obtuse, on the upper side shining, on the under between silky and downy; panicle brachiate, 4-flowered; corolla silky on the outside, smooth in the throat, with its lobes shaggy inside at the point; capsules ovate, longitudinally ribbed, about twice as long as broad. First described by Bonpland as identical with *C. ovalifolia* of the 'Flora Peruviana,' but afterwards recognised by him as distinct. It forms forests in the province of Cuença in Peru. In commerce it is called Cascarilla Peluda, which signifies Velvet-Leaved Quina. Its bark is not in much estimation; it is however a good deal collected for mixing with other sorts, and Bonpland suspects it to be of good quality.

8. *C. magnifolia* (*C. lutescens; C. grandifolia; C. oblongifolia*). Leaves broadly oval, somewhat acuminate, smooth; principal veins of the under side shaggy at the edges; panicle brachiate; corollas silky externally; capsules oblong, tapering, seven times as long as broad. According to Ruiz, Humboldt, and De Candolle, the *C. oblongifolia* of Mutis, which produces the Red Bark of Santa Fé is identical with the *C. magnifolia*, or Flor de Azahar, of the 'Flora Peruviana.' The former grows in 5° N. lat., at the height of from 3600 to 7800 feet above the sea, and is particularly common about Mariquita; the latter occurs in the hottest parts of the Andes of Peru, about 10 degrees south of the line. *C. oblongifolia* of Santa Fé produces a bark which, although less efficacious than that of *C. Condaminea* and *C. lancifolia*, is nevertheless better than that of *C. pubescens;* but this is hardly reconcilable with Pöppig's statement that the *C. magnifolia* has a woody bark, not very astringent, and is chiefly used for purposes of adulteration: he adds, that the bark-peelers do not even reckon it a fever bark, or Cascarilla, but name it simply Corteza del Azahar. This last-mentioned author describes the tree as very stately, with unusually large white flowers, diffusing a delicious odour like that of orange-blossoms; possibly the differences adverted to are the result of climate.



Cinchona Humboldtiana.

9. *C. macrocarpa* (*C. ovalifolia*, Mutis). Leaves elliptical, leathery, on the upper side perfectly smooth, on the under between hirsute and pubescent; panicle trichotomous; corollas with closely pressed down on the outside; the lobes hairy inside; capsules cylindrical, twice as long as broad. The White Bark of Santa Fé. The tree grows between 3° and 6° N. lat., at heights between 4200 and 8400 feet. A variety of it, with leaves quite smooth on both sides, is common near Santa Martha.

10. *C. crassifolia*. Leaves oblong, rather blunt, tapered to the base, leathery, smooth on each side; when young shaggy in the axils of the veins; stipules membranous, grown together; corymbs terminal, trichotomous; branches 2-edged, few-flowered; fruit oval-oblong, three times as long as broad, crowned by the calyx. Found about Quito and Loxa; distinguished from *C. macrocarpa* by its peculiar membranous stipules. Nothing is known of its bark.

11. *C. dichotoma*. Leaves oblong-lanceolate, smooth, when first unfolding rather silky; peduncles terminal, dichotomous, in loose few-flowered corymbs; capsules linear, cylindrical, slender, fourteen times longer than broad. Found on the Andes of Peru, in groves near Pueblo-Nuevo, in the district of Chicoplaya. Its bark is described as brown, intensely bitter, with a little acidity. This and the foregoing species Dr. Lindley places with those imperfectly known.

12. *C. acutifolia*. Leaves ovate, acute, smooth, the veins of their under side somewhat shaggy; panicle brachiate, stalked; corolla silky outside, woolly inside; capsules oblong, tapering to the base, four times as long as broad. A native of the lower woods of the Andes of Peru, in Chicoplaya. The bark is stated to be called Cascarilla de Hoja Aguda: it is moderately bitter. Ruiz says it does not deserve any attention for medical purposes.

13. *C. micrantha* (*C. parviflora*). Leaves broadly oval, blunt, smooth, rather downy underneath at the base of the veins; panicle very large, brachiate, many-flowered; corollas densely silky; capsules oblong, three times as long as broad. A species inhabiting the cold elevated parts of the Andes of Peru, especially about the village of San Antonio de Playa Grande; the inhabitants call its bark Cascarilla Fina. The tree is of considerable circumference, flowers in February, and frequently yields eight to ten arrobas of dry bark, sometimes

called Cascarilla Provinciana, which differs from that of Huanuco by its decided whitish colour and greater roughness of the surface. It is thicker and more woody, the fracture is more fibrous, and the colour is of a bright cinnamon-brown. A bark, called Pata de Gallinazo, from the numerous specimens of Graphis, a forked sort of Lichen, found on its surface, is yielded by this sort, as well as three others. Reichel considers the samples which Pöppig brought home as undoubtedly belonging to the Huanuco Bark of commerce. Its taste, which is at first acid, becomes afterwards a powerful and permanent bitter. Lindley regards this species as identical with *C. scrobiculata.*

14. *C. glandulifera* (*C. glandulosa*). Leaves ovate-lanceolate; on the upper side smooth and shining, with glands at the axils of the veins; on the under side shaggy, especially upon the principal veins; panicles somewhat corymbose; corolla velvety on the tube, woolly in the inside of the limb; capsules oblong, three times as long as broad. The flowers are three lines long, and of a pale rose-colour. This tree only inhabits the higher mountains of Peru, and is more scarce than many of the other kinds; its trunk is from 12 to 15 feet high, and its flowers, in the month of February, fill the forests with their perfume. On the colder parts of the mountains it becomes a bush, the greatest produce from which is five or six pounds of bark. It is considered, according to Pöppig, one of the finest sorts of *Cinchona;* he says that the Peruvians distinguish it by its blackish rind, which is only here and there interrupted by small shagreen spots when in a fresh state. The common people consider these blotches an integral part of the bark, and look upon it as the more valuable if beneath the larger spots there appears a black shining velvety substance dispersed in ovals of some lines broad; this is probably caused by some Byssus. The bark-gatherers hence call it Cascarilla Negrilla. When broken, it exhibits a glossy, shining, almost resiny fracture of a ripe orange-colour passing into a fiery-brown. A variety of it, called Casc. Provinciana Negrilla, is obtained from the trees growing in warm valleys. According to Mr. Reichel, this bark is equal to the finest sort from Loxa, but it is not known in Europe, except in mixture with other kinds.

** Corollas smooth externally.

15. *C. caduciflora* (*C. magnifolia*, Humb.). Leaves oval, smooth, erect, hairy in the axils of the leaves; panicle brachiate, with corymbose branches; corolla smooth, falling off very quickly; capsules oblong, four times as long as broad. Found near Jaen de Bracamorros, a hot damp country, where it is called *C. bora.* The tree is described by Bonpland as being above 100 feet high; its bark is not employed.

16. *C. rosea* (*C. fusca*). Leaves oval, tapering to the base, bluntly acuminate at the point, smooth on each side; panicles clustered, branches corymbose; corolla smooth on the outside, its limb downy above; capsules oblong, three times as long as broad. This occurs not unfrequently about Cuchero, where it forms a highly beautiful tree, which in its size and ramification may be justly compared with the White Beech of Europe. In July it is covered with innumerable pale violet flowers, whence it has obtained the name of Palo de San Juan. Its bark is not collected, but Pöppig thinks it would be found to possess good qualities.

In addition to these species, Dr. Lindley recognises in his 'Flora Medica' the following:—

C. lucumæfolia, Pavon (*C. stupea*). A species said to furnish a part of the Loxa Bark.

C. lanceolata 'Fl. Per.' Ruiz suspects this species to be the true source of the Calisaya Bark. It is found in the districts of Muña, Panas, Pillao, and Cuchero.

C. rotundifolia, Ruiz and Pavon, MSS. From a specimen in Mr. Lambert's Museum. Found at Loxa in Quito.

C. cordifolia, Mutis, MSS. Found in the mountains of New Granada, at an elevation of from 5000 to 8000 feet above the sea.

C. hirsuta, 'Fl. Per.' It is probable this species yields some of the fine Yellow Bark of the shops. It is found in high and cold places near Pillao and Acomayo.

C. villosa, Pavon (*C. Humboldtiana*, Lambert). Found at S. Jaen de Loxa.

C. oblongifolia, Lambert. Although nothing is known of this plant beyond the specimens in the Lambertian Museum, the London College of Physicians, in their 'Pharmacopœia' of 1836 recognised it as yielding one of the barks of commerce.

C. acutifolia, 'Fl. Per.' It is found in the lower groves of the Peruvian Andes, in Chicoplaya, by the river Taso. It yields very poor bark.

C. stenocarpa, Lambert. From Jaen, in the mountains of Loxa.

C. cava, Pavon. From Quito.

Whatever may be the botanical history of the different kinds of bark, on their arrival in Europe they are known by names which have reference rather to their physical appearance or the place whence obtained, than to the botanical characters of the trees which furnish them. In England they are classed under three heads—pale, yellow, and red barks. Of each there are several varieties, which comprehend however, various barks, not the produce of any of the genuine species of *Cinchona* above enumerated, but obtained from species of *Exostemma, Buena*, and *Strychnos* (according to Mr. Burchell). These last, called false or spurious Cinchona barks, are all distinguished from the true Cinchona barks by the absence of Cinchonia, Quinia, and Aricina (or Cusco-Cinchonia, a principle found in the Cusco or Arica Bark, referred to the *Cinchona rubiginosa*, Bergen). Several of these spurious barks are employed in fever and other diseases, but they are chiefly used to adulterate the more valuable kinds of Cinchonas. Even when there is no intermixture of these inferior sorts, a variableness in quality occurs in the bark of the same species, according to its place of growth. The finer kinds are known by experienced persons by a glance of the eye; but it is extremely difficult to indicate, by any description, the marks by which they are guided. All kinds arrive in Europe in the same package, either a chest or serone, which is formed of pieces of wood rudely fastened together, and covered with the hides of animals. They are afterwards sorted, and bring very different prices in the markets, according to the degree of estimation in which each kind is held. We shall describe the best kind only of each; but we must remark, that much prejudice exists on this point, and sometimes excellent kinds are rejected, while inferior sorts are prized. To meet these prejudices, the barkers employ various artifices, more or less injurious. The most useful classification of barks is that proposed by Geiger, which has reference to the relative proportions of their alkaloids:—1. Those in which Cinchonia predominates: chiefly pale or brown barks.—2. Those in which Quinia predominates, of which there is only one—the yellow bark of English commerce, called *China regia vera, China Calisaya.*—3. Those in which Cinchonia and Quinia exist in nearly equal proportions, red barks, and the yellow bark of continental writers; the China of Carthagena of the French, *China flava dura, Quina amarilla.* This last is also called orange bark (*Quina aurantiaca* of Mutis), which is not the yellow bark of English commerce, though by some it is erroneously so considered; and hence the frequent error in the British Pharmacopœias of referring yellow bark to the *C. cordifolia* (Mutis).

Of the Pale Barks three varieties are known in English commerce:—1. Crown or Loxa Bark.—2. Gray, Silver, or Huanuco Bark.—3. Ash Bark. These are always quilled, and never in flat pieces. The powder, which gives the name, varies from gray to fawn-colour.

1. The first variety, Crown or Loxa Bark, called also True Loxa Bark, is obtained either exclusively from the *C. Condaminea*, or from it and *C. scrobiculata.* It occurs in pieces from six to fourteen inches long, the quills varying in diameter from the fourth or even smaller part of an inch to nearly half an inch; the rolls are sometimes double, meeting at the centre: the diameter of the bark is from a quarter of a line to a line and a half. The colour of the exterior is marked dark gray, in some specimens verging to brown. A shining but peculiar appearance is observable upon it, owing to the thallus of the lichens spreading over it. This commonly alternates with the colours of other lichens, grayish-white, yellowish-white, bluish-white, so that the bark acquires an appearance as if it were painted. Numerous transverse cracks, often extending from one side of the bark to the other, with the edges a little raised, are seen, sometimes close to each other, sometimes more remote, especially in the larger pieces, in which also they rarely extend to the whole circumference of the piece. In the larger pieces longitudinal cracks are observed, and between these warts or knots frequently arise, which give a very rough feel to such specimens. The *Usnea florida*, and some foliaceous lichens, such as *Parmelia perforata* (Ach.), often remain attached to it. The inner surface is smooth, except some delicate, irregularly-longitudinal fibres: the colour is a cinnamon or darker brown. The fracture of the smaller quills is even, or slightly fibrous; that of the larger pieces more so, the fibres firm, but neither oblique nor vitreous, as in the yellow bark (*China regia*); but the outer circle presents a resinous aspect. The odour resembles that of tan. The taste at first is slightly astringent, and faintly acid; afterwards very astringent, somewhat bitter, but not acrid.

In respect to its chemical composition, this variety is commonly supposed to contain Cinchonia (discovered in pale bark by Dr. Duncan, jun.) only; but this is a mistake, and it is most probable that the specimens which, when analysed, yielded no Quinia, were either very thin quills obtained from young branches or trees, or were specimens of Huanuco Bark. Bucholz analysed sixteen ounces of the Loxa Bark of commerce, yet found no Quinia, but some error is reasonably suspected; the other constituents were found to be—

	Drachms.	Grains.
Fatty matter, with Chlorophylle	1	0
Bitter soft Resin (Geiger thinks this contained Quinia)	2	0
Hard Resin (red insoluble colouring-matter)	12	0
Tannin (with trace of Acetic Acid)	3	0
Cinchonia	0	28
Kinic Acid	1	30
Hard Resin, with Phyteumacolla	1	49
Tannin, with Chloride of Lime	4	25
Gum	5	40
Kinate of Lime	1	40
Starch, a trace		
Woody Fibre		

The Cinchonia exists in combination with the kinic acid, in the form of kinate of cinchonia. A prejudice exists in favour of the thin quilled pieces, but they are not so well adapted to form extracts, &c., nor to be employed as medicine. Mutis many years ago stated that the thick pieces obtained from branches of middle-aged trees were the most efficacious; and the analysis of Von Santen (in Von Bergen's 'Versuch einer Monographie der China') confirms the correctness of this statement, as far as the relative amount of Quinia yielded by barks of different ages is concerned. From 100 lbs. of Loxa Bark, he obtained of Quinia—

	Ounces.
Thin selected quills	1·042
Moderately thick pieces	4·444
Selected thick pieces, with rough cracked bark	11·104

2. The second kind, Huanuco Bark, termed also Silver or Gray Cinchona, has been known in European commerce only since 1799. The majority of writers on the origin of the barks refer it to the *C. glandulifera.* (Ruiz and Pavon, 'Fl. Peruv.') As it is sent from Huanuco to Lima for shipment, it is also called Lima bark, though some apply the term Lima to a bark supposed to come from the *C. lancifolia* (Mutis). It is likewise called Havanna bark. We have the authority of Pöppig, as stated above, for considering it one of the finest sorts of Cinchona. The variety of it termed Casc. Provinciana Negrilla (the Quinquina Huanuco Noirâtre of the French) is likewise stated by Reichel to be equal to the finest from Loxa, yet it is not known in Europe except in mixture with other kinds. The explanation of which is two-fold: first, that though the trade in this bark was at first very brisk, owing to its excellent quality, the subsequent shipments of it being very inferior, it fell into disrepute; and though it is now again pure and good, still it is necessary to introduce it as Crown Bark. Farther, as the French give the name Lima bark to another kind as above mentioned, probably the dark-ash bark, the dark Ten (*China Pseudo-Loxà*), the false Loxa bark, confessedly a very bad bark, it has caused the genuine Lima bark to be little esteemed. Farther, as the Huanuco Bark is in quills which are larger and coarser than those of the Crown Bark, the prejudice in favour of thin quills operates to the disadvantage of this very excellent sort.

The quills are from three to fifteen inches, generally from four to ten inches long, with a diameter from a few lines to one or even two inches. They are in single rolls, or double and inclosed rolls; the inclosed rolls exhibit spiral windings, and frequently traces of a sharp oblique incision of the knife. This incision is not observed in the case of any other kind, and it is probably made by the Cascarilleros to facilitate the separation of the bark from the trunk of the tree. The diameter of the bark varies from one-fourth of a line to five lines. The epidermis is seldom absent, but now and then portions of it have been rubbed off, and then the rusty surface of the liber is seen. The epidermis is a whitish-gray, but often covered with numerous lichens, chiefly *Glyphis cicatricosa, Graphis duplicata, Porina granulata, Pyrenula discolor, Mastoidea, Pupulo, Lecanora punicea, Parmelia perforata, Sticta aurata,* and *Usnea florida.*

The character of the cracks is more variable than in Loxa Bark, few extending to the whole circumference of the bark; in the young pieces the cracks are not so deep as in the older, in which also the edges are raised, giving a rough appearance to it. Some specimens also between the large and extensive cracks present spaces very slightly cracked, of a golden-straw or leaden-gray colour. Huanuco Bark is distinguished by the brighter colour of its surface, the multitude of its small cracks, and the sharp oblique incisions above mentioned, from the yellow or Calisaya bark (*Quina regia*), and the Loxa bark, to both of which it bears considerable resemblance. The inner surface is of a bright-cinnamon, passing into an ochre-yellow or rusty hue, and is generally rough, and, especially in the thicker quills, fibrous, frequently with portions of the wood of the stem adhering to it. Though no satisfactory chemical analysis has been made of it, exhibiting its entire composition, yet the relative proportions of its alkaloids have been stated. It is the richest in Cinchonia of all the barks hitherto examined. Goebel, Kirst, and Von Santen say that it yields this alkaloid only. Michaelis maintains that two specimens analysed by him yielded, in addition, a little Quinia. The quantity of Cinchonia is very variable. Kirst and Goebel obtained from one pound 168 grains; Von Santen from nine different specimens examined by him, from one pound a quantity varying from $106\frac{8}{9}$ grains to 210 grains. The fracture of the bark is either fibrous or splintery; that of the outer portion resinous. The odour resembles that of clay. The taste acid, astringent, somewhat aromatic; then bitter, acrid, and enduring. The powder is a deep cinnamon-brown.

3. The third kind of pale bark, called Ash, Jaen, or by corruption Ten-Bark, is by Von Bergen referred to *C. ovata* (R. and P.), which he considers synonymous with the *C. pubescens* of Vahl. It is likewise called Pale Ten-Bark to distinguish it from the Dark Ten-Bark, or False Loxa Bark. The quills of this kind are always crooked, frequently also twisted. The epidermis is frequently absent; when present, it presents faint transverse cracks, the edges of which are somewhat raised, and a few longitudinal cracks or warts. The bark itself is of an ash-gray, whitish-gray, or light-yellow colour, with brown or blackish spots. It has often a slightly shining aspect. The inner surface varies very much, sometimes smooth, sometimes with long fibres attached to it, sometimes splintery, of a cinnamon or dark-brown colour. The fracture is sometimes even, sometimes slightly fibrous, with a faint external resinous circle. The odour is a little like tan, and pleasant. The taste slightly acid and moderately astringent, a pure but not disagreeable bitter. The accounts of its chemical composition differ much. Von Santen says it contains neither Cinchonia nor Quinia. Goebel and Kirst from one pound obtained no Cinchonia, but 12 grains of Quinia; while Michaelis says in two specimens examined by him, he found both Quinia and Chinchonia; of the former, even 80 grains; of the làttor, 12 grains. Notwithstanding this last statement, this is generally and justly regarded as a very bad sort of pale bark, and was chiefly used to adulterate the true Loxa Bark.

The Dark Ten-Bark, or China Pseudo-Loxa, occurs generally in thin or middle-sized, but seldom thick, quills. The surface exhibits transverse cracks and longitudinal wrinkles, which often form rings a line or more broad. The colour is milk-white, but covered with so many lichens as to have a dark appearance. The under surface is uneven, fibrous or splintery, the fibres often very long: the colour a rusty brown. The fracture is fibrous or splintery: it exhibits a resinous appearance only when cut. Smells strongly like tan. The taste at first enduringly acid, afterwards astringent. This bark is frequently purchased instead of the true Loxa Bark, and is at present of frequent occurrence in the market. Bergen considers it to be produced by the *C. nitida* (R. and P.) and the *C. lancifolia:* these are perhaps only varieties the one of the other; but whenceever obtained it is very poor in alkaloids, one pound yielding only 9 grains of Kinia and 12 of Cinchonia. It is held to be one of the worst kinds of pale bark.

The lichens and epidermis should be scraped off all pale barks before they are reduced to powder: though they increase the bulk, they diminish the efficiency of the powder.

The Yellow Barks.—There are only three kinds; the Yellow Bark of English commerce, which by continental writers is called merely *China regia, Quina Calisaya* (the Quinquina Royal, Gelbe Königschina), and the Yellow or Carthagena Bark of the Continent comprehending two sorts:—1. China flava fibrosa, China de Carthagena fibrosa, the Quina Naranjada (of the natives); the Quina de Santa Fé fibrosa, or Quina de Carthagena lenosa (fibrosa), of the Spanish; Quina de Carthagena amarella lonhosa (fibrosa) of the Portuguese; Quinquina de Carthagene fibreux, ligneux, Quinquina Orange (of the French); Holzige Gelbe China, Holzige Carthagenarinde (of the Germans). 2. China flava dura, China lutea, China de Carthagena dura, Quina Naranjada de Santa Fé, Quina aurantiaca, Quina de Santa Fé, or Quina de Carthagena dura (Spanish); Quina de Cartagena amarilla dura (Portuguese); Quinquina de Carthagene, or Quinquina flava dura (French); Harte Gelbe China, Harte Carthagenarinde. This is the Orange Bark of Mutis, which he says is obtained from *C. lancifolia.* Bergen and Goebel ascribe it to *C. cordifolia* (Mutis), which some deem synonymous with *C. pubescens* (Vahl.), which species is therefore stated alone to yield the yellow bark; but this only applies to the yellow bark of the Continent, for the source of the Yellow Bark of English commerce must be considered as yet undetermined. We shall limit our description to this last kind, as the best known in this country, and at the same time the most valuable. This occurs in two forms—quills and flat-pieces; the quills were formerly most prized, but all well-informed persons now prefer the flat pieces as much richer in Quinia. The quills are in general in single, seldom in double rolls, the diameter of which is mostly greater than even the largest quills of pale Loxa Bark, being from a quarter of an inch to an inch, the length from 4 to 24 inches, occasionally containing smaller quills inside the larger. The thickness of the bark varies from one-eighth to one-fourth of an inch. The external surface is generally grayish-brown, inclining to blackish, yellowish, or whitish, according to the kind of lichen by which it is beset. Few pieces are quite free from lichens; many specimens exhibit the wax-yellow thallus of *Lepra flava* (Acha.), which appears as if fused upon it: this is a very characteristic mark, when present, of Calisaya bark. The quills seldom have the epidermis removed, which has both transverse and longitudinal cracks, which penetrate down to the bark itself, as their traces can be perceived upon it even when the epidermis has been removed. The transverse cracks frequently extend over the whole circumference of the piece, yet they are much interrupted by longitudinal cracks and furrows (this is more especially the case with the thinnest quills); but all of them have raised edges, resembling those of Loxa Bark. Where the epidermis is wanting, the colour of the exposed part is of a cinnamon or rusty-brown hue. The colour of the inner surface varies according to the age of the bark. Generally it is a deep cinnamon, in recent barks verging to reddish; in older specimens it is paler, or a rusty-yellow. The transverse fracture is in the thinner quills smooth, in the larger fibrous, splintery, or vitreous; a resinous circle is under the epidermis. The longitudinal fracture is generally uneven, and delicately fibrous: this kind of bark is easily broken.

The flat Yellow Bark, or that in splints, occurs either with the epidermis, or divested of it (*China regia nuda*). Pieces retaining the epidermis are generally from one to five inches broad, generally quite flat, but sometimes slightly curved, from three to fifteen inches long, and from one quarter to three-quarters of an inch thick. The characters of the epidermis correspond with that above described: the uncoated kind is most frequent, and occurs in splints from one to eight lines thick. The colour varies, but is generally a reddish or rusty-brown, and is nearly the same on both surfaces, so that in pieces which have become convex on the inner side, and concave on the outer, as often happens, it is difficult to determine which was the exterior; this is by far the best kind of yellow bark.

Adulteration of Yellow Bark is not very easy, but a kind of humalia-like bark used to be substituted for it.

The odour of genuine Yellow Bark is slightly that of tan. The taste is faintly acid, strongly but not unpleasantly bitter, aromatic, stimulating, and slightly astringent.

The analyses of uncoated Yellow Bark (Calisaya) by Pelletier and Caventou show its composition to be super-kinate of quinia, fatty matter, slightly soluble red colouring-matter (red cinchonic acid), soluble red colouring-matter (more than in gray bark), tannin, kinate of lime, lignin, amylum. When the uncoated kind is analysed, some Cinchonia is obtained. By a comparative analysis it is found that a pound of flat uncoated yellow bark yields nearly twice as much Quinia as the quilled sort, a point of much importance to the preparers of that alkaloid. The Carthagena yellow barks both contain Quinia, but in less quantity than the Calisaya bark; the hard Carthagena bark, in addition, yields Cinchonia, but not the fibrous kind.

The Red Bark, of which one kind only is known in English trade, is generally referred to *C. oblongifolia;* though many doubts may be held on this head. Bergen is much more disposed to consider the *C. oblongifolia* as the source of the China Nova, or Surinam bark, which is not officinal in Britain; this also is doubtful. Red bark has been known for 130 years, but was not much used in Europe till 1779. It occurs in quills and flat pieces, most frequently in the latter form. The quills are rolled singly, or doubly, from 4 to 15, but generally from 4 to 6 inches long, and from a few lines to 1 inch in diameter, the bark being from 1 to 4 lines thick. The figure of the flat pieces is variable, being generally very much broken, frequently with the epidermis entire; but this is often partially, seldom or never completely, absent. The length is generally from 4 to 24 inches, the thickness from ¼ to 1 inch, and the breadth 1 to 3 inches. The quills most frequently have the epidermis entire; some of them have a whitish-yellow, or grayish-white epidermis (interrupted by longitudinal and irregularly transverse cracks), a red hue shining through it. In fact, even in pieces with the epidermis entire, and covered with many lichens, the red hue is seen over shining through —a characteristic mark of this kind of bark. The flat pieces have generally an amazing number of lichens upon them. In these pieces also what is called the rete mucosum is often very spongy. Warty bodies are found on some varieties. The inner surface is a reddish-brown, varying in intensity. The fracture in thin quills is smooth, in those of a moderate thickness fibrous, and in thick quills and flat pieces fibrous and splintery: the epidermis, when penetrated by the resinous principle, exhibits a vitreous shining ring.

Pelletier and Caventou analysed a specimen of the variety free from warts, and found it to contain—

Superkinate of Quinia } in large quantity.
Superkinate of Cinchonia }
Slightly soluble red colouring-matter, or red Cinchonic Acid.
Soluble red colouring-matter (tannin).
Yellow colouring-matter; fatty matter.
Kinate of Lime. Woody Fibre. Starch.

The relative proportions of Quinia and Cinchonia differ in different specimens; a pound of bark yielding in some instances 70 grains of Cinchonia and 77 grains of sulphate of quinia, in others 184 grains of Cinchonia and only 9 grains of sulphate of quinia.

The Humalies, or Brown Bark, is not known in English commerce; its source is not accurately determined.

Several inferior kinds, and others erroneously reputed to be Cinchona barks, are met with, either accidentally or fraudulently mixed with or passed for the genuine; but they may be known by not possessing the characters of the best kinds as given above.

Dr. Lindley, in his 'Flora Medica,' gives the following as the result of his inquiries with regard to the barks used in medicine:—

(a). *Pale Barks:—*	
Crown, or Loxa Bark	*C. Condaminea.*
Silver, Gray, or Huanuco Bark	*C. micrantha.*
Ash-Bark	(?)
White Loxa Bark	(?)
(b). *Yellow Barks:—*	
Yellow Bark	*C. lanceolata.* *C. hirsuta.* *C. nitida.*
Calisaya	*C. lanceolata.*
Carthagena Bark	*C. cordifolia.*
Cusco Bark	(?)
(c). *Red Barks:—*	
Red Cinchona, or Bark of Lima	(?)
Cinchona Novex	*C. magnifolia.*
(d). *Brown Barks:—*	
Humalies Bark	*C. purpurea.*

In the 'London Pharmacopœia,' published by the College of Physicians for 1851, the following Barks are recognised:—

C. flava (regia), (*C. cordifolia,* 'Ph.' 1836) .	*C. Calisaya,* Weddell.
C. pallida (de Loxa), (*C. lancifolia,* 'Ph.' 1836)	*C. Condaminea,* Weddell.
C. rubra (*C. oblongifolia* 'R.' 1836) . .	*C. species incerta.*

CINCHONA'CEÆ, *Cinchonads*, the Cinchona-Tribe, a natural order of Monopetalous Exogenous Plants, with an inferior fruit, a regular corolla, seeds containing a small embryo in the midst of horny albumen, and opposite undivided leaves with stipules placed between their petioles. This brief character distinguishes a most extensive and important assemblage of plants, comprehending many of the most useful species we are acquainted with. The bark of the order is very generally tonic, aromatic, and febrifugal, and its energy is attested by the well-known use of that of *Cinchona* itself, to say nothing of the numerous other genera fit to be employed as substitutes for Jesuit's Bark. [CINCHONA.] The albumen of the seeds when roasted affords, in the case of coffee, a fragrant, stimulating, and agreeable principle [COFFEA]; and the roots of many herbaceous kinds possess active emetic properties. True Ipecacuanha is the produce of *Cephælis Ipecacuanha* [CEPHÆLIS], but many other Cinchonaceous plants resemble it in their medicinal qualities, and are perhaps mixed with it in commerce. *Cinchonaceæ* are the *Rubiaceæ* of many botanists; but as it appears advisable to separate *Rubia* and its allies into a distinct order, on account of the absence of stipules, and for other reasons [STELLATÆ], it is necessary to alter the name of the remainder of the group; and as a type of the order, when circumscribed, *Cinchona* is unexceptionable.

The Honeysuckles were also referred to *Rubiaceæ*, but are now separated under the name of *Caprifoliaceæ*. With these two orders *Cinchonaceæ* has undoubtedly the greatest affinity. It is also related to the *Compositæ*, and through the genus *Lygodysodea* to the *Umbelliferæ*. Some of the genera of this order exhibit a tendency in their sepals to revert to the foliar condition after the petals have fallen. This is the case with *Mussænda* and *Calycophyllum*. [CALYCOPHYLLUM.]

Cinchonads are found exclusively in the hotter parts of the world, where they are so common as to constitute not less than one-twenty-ninth part of the whole of the vegetation. The order comprises 269 genera and 2500 species. The most valuable of these are undoubtedly the species of *Cinchona*, but many important plants besides these are yielded by this order. The genera *Pinckneya, Condaminea, Guettarda, Antirhea, Morinda, Hymenodictyon*, and *Ophiorhiza*, all afford species which yield barks regarded as febrifuge and astringent in the treatment of disease. Some of the species yield tannin, as the *Uncaria Gambier*, from which a kind of Catechu or Kino is prepared. The species of *Chiococca* [CHIOCOCCA] have active properties. Only a few species yield food. "The Genipap, a South American fruit, as large as an orange, of a whitish-green colour, but containing a dark-purple juice, with an agreeable vinous taste, is borne by *Genipa Americana*. *Sarcocephalus esculentus* is the edible peach of Sierra-Leone. *Vangueria edulis*, or Voa-vanga is said to be a good dessert fruit in Madagascar. *Genipa Brasiliensis* is also eaten in Brazil, but Martius says that it is only fit for table after becoming bletted, and that it is better when preserved with sugar than when fresh. Some of the bushes called in Tasmania native currants are Coprosmas, but they are not of good quality." (Lindley).

Several genera, as *Oldenlandia, Psychotria, Genipa, Condaminea*, and *Hydrophylax*, yield colouring-matters used in dyeing. Some species are remarkable for their fragrance and beauty, especially amongst the genera *Gardenia, Hindsia, Posequeria, Ixora, Bouvardia, Catesbæa.*

(Lindley, *Vegetable Kingdom.*)

CINCINNURUS. [BIRDS OF PARADISE.]

CINCLOSO'MA, a group of Thrushes, characterised by Dr. Horsfield and Mr. Vigors. [MERULIDÆ.]

CINCLUS, a genus of Insessorial Dentirostral Birds, belonging to the family *Merulidæ*. *C. aquaticus* is the Common Dipper of British ornithologists. [MERULIDÆ.]

CINERA'RIA, a genus of Plants belonging to the natural order *Compositæ*, the sub-order *Corymbiferæ*, the tribe *Eupatoriaceæ*, the sub-tribe *Senecioneæ*, and the division *Eusenecioneæ*. It closely resembles *Senecio* [SENECIO], and differs from that genus in its involucre being composed of one row of equal scales only. Two species are found in Great Britain.

C. palustris, a shaggy plant with a much branched stem which is corymbose above; leaves broadly lanceolate, half-clasping, the lower leaves sinuate-dentate. It has a stem 3 feet high, thick, hollow, and leafy. The florets are of a bright-yellow colour. It inhabits ditches in fenny districts, and was at one time a more abundant plant in England than it is at present.

C. campestris, a shaggy plant, with a simple stem; the root-leaves oblong, nearly entire, narrowed below; the stem-leaves lanceolate, heads corymbose, involucre woolly below nearly glabrous in the upper half; the fruit hispid. It has a stem 6 or 8 inches high with yellow florets. It is found mostly on chalk downs. A variety, *C. c. maritima*, occurs near the sea in very wet seasons; it is then twice or three times as large as usual, and the lower leaves are dentate.

(Babington, *Manual of British Botany;* Lindley, *Natural System.*)

CINERAS, a genus of Barnacles. [CIRRIPEDIA.]

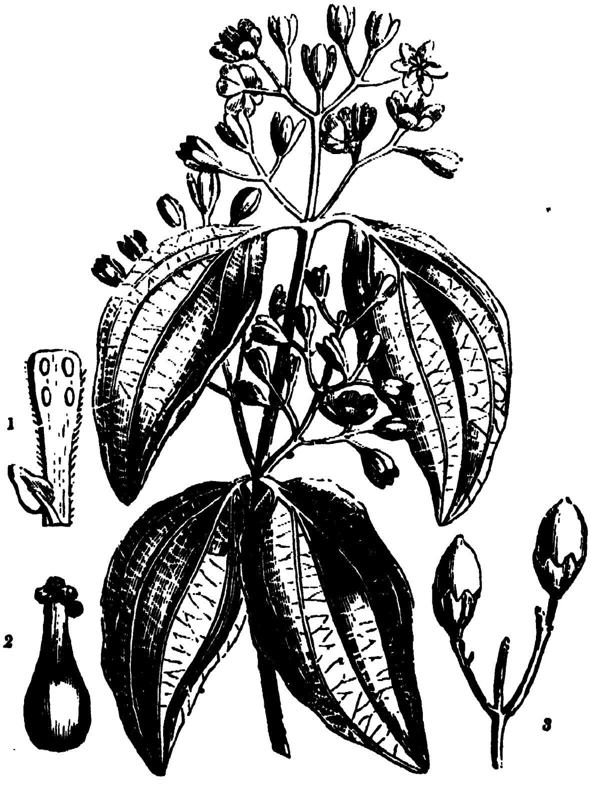
CINNABAR. [MERCURY.]

CINNAMODENDRON, a genus of Plants referred to Von Martius's doubtful order *Canellaceæ.* This genus has been separated from *Canella* which is well represented by *C. alba*, a common West Indian aromatic shrub with evergreen coriaceous obovate alternate stalked leaves, no stipules, and corymbs of purple flowers. *C. alba* is often called Wild Cinnamon in the West Indies, on account of its warm aromatic fragrant properties. [CANELLA, in ARTS AND SC. DIV.) There is but one other species of *Canella. Cinnamodendron* has but one species, *C. axillare.* It is a Brazilian tree with aromatic properties. Its bark is used as a tonic and stimulant. It is administered in low fevers and relaxed sore throat.

CINNAMO'MUM, a genus of Plants belonging to the natural order *Lauraceæ.* It is confined to the East Indies, and distinguished from the rest of its natural order by the following technical character :—Flowers hermaphrodite; abortive stamens perfect; anthers with four cells; limb of the perianth articulated, deciduous; buds of the leaves incomplete; leaves evergreen, often approximated in pairs, 3-ribbed or triple-ribbed. It contains several species, some of which yield Cinnamon, and others Cassia, two aromatic barks which appear to differ from each other in little, except in the degree in which the aromatic principle exists in them. Till lately it was understood that a Ceylon plant called *Laurus Cinnamomum* yielded true Cinnamon, and another, called *Laurus Cassia*, produced the inferior Cassia bark on the coast of Malabar; but, according to Nees von Esenbeck, at least two distinct species yield the Cinnamon of the shops, and it is altogether uncertain which out of several yields Cassia.

Cinnamon has been known to European nations from very high antiquity. The Greeks procured it, together with the name, as Herodotus (iii. 111) remarks, from the Phœnicians, who are by some supposed to have formed the name Kinnamomon from Kagu-manis, or Kaschu-manis, two Malayan words signifying sweet wood ('Annals of Philosophy,' 1817); and Cassia itself may have originated in the same word Kaschu, 'wood.' That which is now chiefly consumed in England is the aromatic bark of a small tree found in the Island of Ceylon.

C. Zeylanicum, the Ceylon Cinnamon-Tree. Its leaves are of an oblong figure, generally more or less heart-shaped at the base; of a thick leathery texture, very smooth and shining on the upper side, glaucous and beautifully marked with prominent netted veins on the under side; they are always blunt, and seldom even tapered to the point; they are nearly opposite on the branches, and are traversed by from three to five ribs, of which the lateral ones run in a curved direction from the base to the point. The flowers are greenish-white, and appear in threes, collected in clusters, in small terminal panicles; they are composed of a downy calyx divided into six parts, and containing nine perfect stamens and nine others which are imperfect and resemble yellow triangular-stalked glands. Their pistil is a roundish 1-celled body terminating gradually in a style with a white downy capitate triangular stigma. The fruit is an oval berry, not unlike an acorn, seated in the calyx, which is enlarged and converted into an angular 6-toothed cup. The tree is supposed to produce a considerable number of varieties to which native names are given, but it is uncertain whether these are not, in part at least, distinct species. In addition to the aromatic oil contained in its bark, the root of the Cinnamon-Tree yields camphor; the liber, oil of cinnamon; the leaves, oil of cloves; and the fruit a peculiar trebintaceous ethereal oil. When the branches are peeled the finest sticks of Cinnamon are said to be obtained from the liber of the middle-size branches, an inferior sort from the youngest shoots, and that which is produced by the thickest branches is considered of very little value.

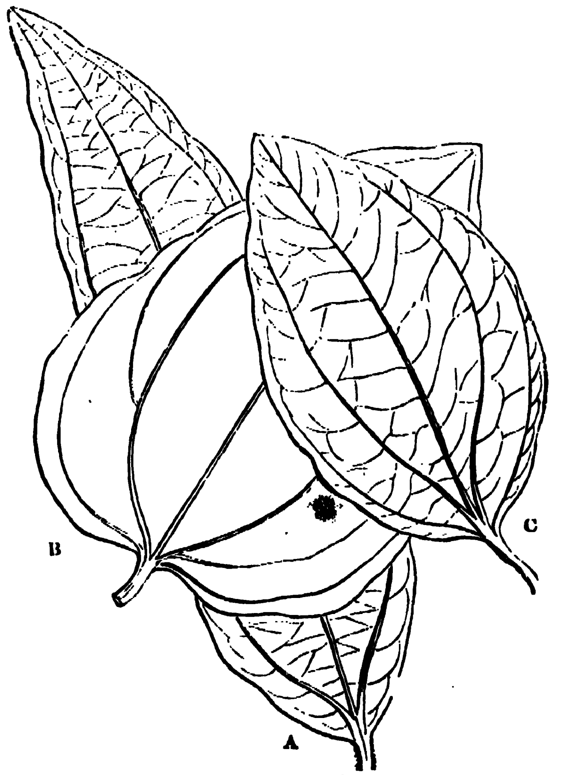


Ceylon Cinnamon-Tree (*Cinnamomum Zeylanicum*).

1, a perfect stamen, with one of the abortive stamens at its base; 2, a pistil; 3, ripe fruit.

It is said to require a rich sandy soil mixed with vegetable earth. Some degree of shade is necessary to the young plants, which therefore are not cultivated in open plains, but in spaces in the woods where a few large forest-trees are left scattered about to shade them. In about six or seven years from the time they are sown, young cinnamon bushes are from four to six feet high; they are not however generally barked before the ninth year. The cinnamon peeling begins in May, at the end of the rains, and lasts till November; the operation of peeling consists in nothing more than slitting the bark longitudinally and then cutting it across, so that it can be readily turned back from the wood, and it is the more easy in consequence of the shoots which are cut for peeling not being more than three years old.

C. aromaticum (Esenbeck), is the species which is believed to be the Cinnamon of China and Cochin China. This plant, which is not uncommon in the hot-houses of Europe, has long been reputed the kind that yields cassia, but that opinion appears to be altogether unfounded. It is said to grow in the dry sandy districts, lying north-west of the town of Faifoe, between 15° and 16° N. lat. The leaves are very much larger than in the true Cinnamon, they usually hang down from the stalks, have never more than three ribs, and never are in any degree cordate at the base; sometimes they are taper-pointed, sometimes blunt. A, in the following figure, is a leaf of this species; B and C are different forms of the leaf of the *Cinnamomum Zeylanicum*, The aromatic fruits called Cassia-Buds are also yielded by this species. [CASSIA-BUDS.]



With regard to *Cassia lignea*, or Cassia-Bark, it seems altogether uncertain what it is that yields it; whether it is some peculiar species, as it has long been supposed to be, or inferior samples of Cinnamon gathered in unfavourable seasons, or from trees growing in bad situations. The differences in Cassia-Bark are of such a nature as to render the last the most probable conjecture; it possesses less aromatic oil, a circumstance likely to occur to trees in unfavourable situations; and in proportion as the oil disappears there is an increase in mucilaginous and resinous matter. But on the other hand there are so many inert or comparatively inert species of *Cinnamomum*, that Cassia may very well belong to one of them. There is *C. dulce* in China, *obtusifolium, iners, Bazania*, and others, any of which may possibly yield such a bark. The question is however one more of curiosity than real consequence. The only important thing about Cassia was the supposing it to be furnished by what is really a most valuable species, and that error is now removed.

Cinnamon of the genuine Ceylon kind is cultivated in Guyana, the island of St. Vincent, the Cape de Verd, Brazil, the Isle of France, Pondicherry, Guadaloupe, and elsewhere, and it is said that plants obtained from Paris by the Pasha of Egypt have thriven when transported to Cairo. There is however no probability that the tree will succeed as an article of commerce in any country that has not the hot damp insular climate and bright light of Ceylon.

C. Tamala is a native of the continent of India, wild in Derwanee and Gongachora, cultivated in the gardens of Rungpoor. The taste of the leaves when dried is aromatic; they are sold in the shops under the name of Folia Malabathri Tamalapathri or Indi.

C. Loureirii grows on the lofty mountains of Cochin China, to the west towards Laos, Japan. The flowers of Cassia are produced by this species. The old and young branches are worthless, but the middle-sized shoots are superior to that of Ceylon, and are sold at a much higher price.

C. Culilawan is a native of Amboyna, especially in Leitimoo near the villages of Saya, Rutton, and Ema. The bark when dry is aromatic like cloves, but less pungent and sweeter. It has some astringency, and owes its medicinal activity to a combination of volatile oil, resin, and bitter extractive. It is useful in dyspeptic complaints, diarrhœas, &c. The natives of Amboyna use it both as an internal medicine and as a stimulating linament.

C. rubrum grows in Cochin China, and contains an essential oil, like the last species, smelling of cloves, but not so agreeable.

C. Sintoc grows on the Nilgherry Mountains in Hindustan, and the higher mountains of Java. It is a tree 80 feet high. The bark is in quality very like the true Culilawan, but not so agreeable; it is more bitter and drier, and more powdery when chewed.

C. xanthoneuron is a tree growing on the Papuan Islands and the Moluccas. The bark has great fragrance when fresh, but loses this quality in time. It is so extremely like Mapoy Bark as to be confounded with it.

C. nitidum is a shrub or small tree growing on the continent of India. It is the plant which furnished the principal part of the 'Folia Malabathri' of the old pharmacologists.

C. Javanicum is a tree with a trunk 20 feet to 30 feet high, growing in Java and Borneo. The bark is of a deep cinnamon-brown colour, more bitter than Culilawan Bark, and the leaves when rubbed have a very sharp aromatic odour. Blume says the bark deserves the attention of medical men on account of its powerful anti-spasmodic properties.

With regard to Cinnamon and Cassia Barks as they occur in commerce, we are most indebted to Nees von Esenbeck, who has paid great attention to the subject. According to him, the finest or Ceylon Cinnamon is procured from the three-year-old branches of the *Cinnamomum Zeylanicum* (Blume), which is found native in the island of Ceylon only; the cultivation however has been extended to Java and to South America. Though found in various parts of the island, it is most abundant in the south-west part, near Colombo, and yields the best Cinnamon when growing in a sandy quartz soil. The time for stripping off the bark is from May to October. The bark, after being removed from the branches, is tied up in bundles for twenty-four hours, during which time a sort of fermentation takes place, which greatly facilitates the separation of the outer part of the bark from the cuticle and epidermis, which is very carefully scraped off the Ceylon Cinnamon. It is then rolled up into quills, or pipes, about three feet in length; the thinner or smaller quills being surrounded by larger ones—a mark which always distinguishes Cinnamon from Cassia. It is then conveyed to Colombo, where it is sorted by government inspectors into three kinds, of which the two finest alone were allowed to be exported to Europe, while the third, or inferior kind, was reserved to be distilled along with the broken pieces of the other two for the purpose of obtaining the oil of cinnamon. The select Cinnamon is formed into bales of about 92½ lbs. weight, containing some pepper or coffee, and wrapped in double cloths made of hemp, and not, as stated by some writers, of the cocoa-tree.

This fine Cinnamon occurs in pieces about forty inches in length, generally containing from six to eight rolls or quills in each, one within the other, of the thickness of vellum paper, of a dull golden-yellow colour, smooth on both outer and inner surface. It is very fragrant, agreeably aromatic, taste pleasant, warm, aromatic, slightly astringent. Analysed by Vauquelin, it yielded volatile oil, tannin in large quantity, an azotised colouring-matter, a peculiar acid, mucilage, and fœculum.

The root of the Cinnamon tree yields a kind of camphor, and the leaves yield an oil which resembles oil of cloves, which it is often used to adulterate. This is quite distinct from the oil of cinnamon obtained from the bark. The ripe berries yield by decoction a solid volatile oil, similar to the oil of juniper. Cassia, according to Marshall and others, is the bark of the old branches and trunk of the *Cinnamomum Zeylanicum* already mentioned, while others assert that it is the bark of an entirely different species, namely, of the *Cinnamomum Cassia* (Nees Fratres, et Blume), a native of China, but cultivated in Java. This last view is much the more probable; for not only is no Cassia exported from Ceylon (except the rejected or third sort of Cinnamon, which is introduced into England incorrectly under that name), but almost all the Cassia which reaches Europe comes from Canton. Reagents produce very different effects both on the infusion and oil of these two barks, which is a rational ground for believing them to be obtained from different species.

Cassia is easily distinguished from Cinnamon. The bales in which it arrives are much smaller, containing only from two to four pounds, bound together by portions of the bark of a tree. The quills are thicker, rolled once or twice only, and never contain thinner pieces within; the diameter of the bark is much thicker than that of Cinnamon, and harder, the outer rind less carefully removed (large patches of the cuticle and epidermis often remaining upon it), the colour deeper, of a brownish fawn-colour (that raised in Guyana is yellowish), with the odour of Cinnamon, but fainter and less grateful; the taste more acridly aromatic, pungent, less sweet, at the same time more powerfully astringent, yet mucilaginous.

Cassia is often substituted for Cinnamon, and it is also frequently adulterated with Cassia Lignea (which is the bark of a degenerate variety of the *Cinnamomum Zeylanicum* (Blume) growing in Malabar, Penang, and Silhet), with the bark of *Cinnamomum Culilawan*, and with portions which by distillation have been deprived of their volatile oil.

Oil of Cinnamon is obtained chiefly from the fragments which fall from the quills during the inspection and sorting at Colombo. These fragments are coarsely powdered, and after being immersed for forty-eight hours in sea-water, are distilled, when a milky fluid comes over, which separates into two parts, a light oil which floats, and a heavy one which sinks in the water. Eighty pounds weight of Cinnamon yield about two ounces and a half of light oil, and five ounces and a half of heavy oil. About 100 gallons of oil of cinnamon are annually obtained at Colombo. As the oil which is met with in commerce is a mixture of these two, the specific gravity is variable, 1·035 to 1·090. In time a spontaneous separation takes place, and there are formed beautiful transparent crystals of a stearoptin, or Cinnamon-Camphor. Sometimes benzoic acid is formed. Oil of Cassia is also obtained by distillation; at first it is whiter than oil of cinnamon, afterwards it becomes yellow, but never of such a fiery yellow as cinnamon-oil. The odour is agreeable, but not so delicate and cinnamon-like: taste, acrid, burning, but different from cinnamon. Specific gravity 1·0608; it reddens litmus paper. At a low temperature crystals show themselves, which disappear with an increase of heat. Some consider these a camphor, others benzoic acid. Benzoic acid unquestionably exists in this oil. Oil of cinnamon is adulterated with oil of cassia, with the oil of cassia-buds, with the oil of the *Cerasus lauro-cerasus*, or Cherry-Laurel, and it is also said with oil of bitter-almonds, an exceedingly dangerous intermixture.

CINNAMON-STONE. [GARNET.]

CINNAMON, WILD. [CINNAMODENDRON.]

CINNYRIDÆ, a family of Passerine Birds of brilliant plumage, living upon the juices of flowers, and representing in the Old World the *Trochilidæ*, or Humming-Birds of the New Continent and its islands. They are known by the common names of Sun-Birds and Soui-Mangas.

Cuvier, in defining his genus *Cinnyris*, states that the species composing it have the tail no longer worn; the bill long and very slender, with the edge of the two mandibles finely serrated; and the tongue, which can be protruded from the bill, terminating in a fork. They are, he observes, small birds, the plumage of whose males glitters in the season of love with metallic colours, approaching in splendour that of the Humming-Birds, which they represent in this respect in the Old Continent, where they are found principally in Africa and the Indian Archipelago. They live, he adds, on flowers, from which they pump the juices: their nature is gay, and their song agreeable. Their beauty makes them much sought after in our cabinets; but as the plumage of the females and that of the males during the interval between the seasons of love is entirely different from its nuptial brilliancy, it is difficult to characterise the species. ('Règne Animal.')

Cinnyris, in Cuvier's arrangement, stands between *Melithreptus* and *Arachnothera*.

Mr. Vigors considers the *Tenuirostres*, or Suctorial Birds, the most interesting group perhaps of the animal world. "Deriving," says that author, "their subsistence for the most part from the nectar of flowers, we never fail to associate them in idea with that more beautiful and perfect part of the vegetable creation, with which, in their delicacy and fragility of form, their variety and brilliancy of hues, not less than by their extracting their nourishment from vegetable juices, they appear to have so many relations. As the tribe is confined exclusively to the torrid zone and the southern hemisphere, the naturalists of our northern latitudes have little opportunity of observing their manners or of inspecting their internal construction. Much confusion has consequently arisen in assigning them their respective stations, more particularly among the Honey-Suckers of Australia, which have been indiscriminately scattered among every group of the order. In the absence of that certain and perfect information which alone can authorise us to decide upon the station of any bird in nature, I cannot, at present, undertake to fill up the details of this tribe with much pretension to accuracy. The following sketch however of the Suctorial Families will, I imagine, be found to afford some approach, in its general outline, to the natural divisions into which the tribe branches out, and to the order in which they succeed each other :—*Nectariniadæ* (?), *Cinnyridæ*, *Trochilidæ*, *Promeropidæ*, *Meliphagidæ*. Arranged according to their typical characters, they thus succeed each other :—

Normal Group.

Bills and feet comparatively slender (gracilioribus)	*Cinnyridæ*. *Trochilidæ*.

Aberrant Group.

Bills and feet comparatively strong (fortioribus)	*Promeropidæ* (?). *Meliphagidæ* (?). *Nectariniadæ* (?)."

Mr. Vigors then proceeds to state that Illiger was the first who separated the true *Certhia* of the present day from the groups of the Linnean *Certhia*, which feed upon vegetable juices, and which he therefore distinguished by the generic name of *Nectarinia*. This latter genus, observes Mr. Vigors, comprising two distinct and strongly marked groups, has again been separated by Cuvier into two divisions: for the first of which, consisting of birds whose bills are shorter and stronger than those of the second, and whose feet are also in general more robust, he has retained the name of *Nectarinia;* while he has distinguished the latter division, where the bills are longer and more attenuated, and the legs and feet are proportionally more delicate, by the appellation of *Cinnyris*. The first two families in the arrangement of Mr. Vigors accord with these views; and he remarks that, besides the difference in their structure, the two groups may be separated by their geographical limits. The *Nectariniadæ*, as far as Mr. Vigors can trace out their extent, are confined to the New World; while the *Cinnyridæ* are circumscribed within the bounds of the ancient continent and its adjoining islands. In looking to the succession of affinities in the tribe, Mr. Vigors remarks that the *Nectariniadæ* appear to hold, by the comparative strength of their feet and bill, an intermediate rank between the Creepers and the typical groups of the present tribe. The *Certhiadæ*, as we have seen [CREEPER], employ, he observes, the feet in climbing; the *Nectariniadæ* hop from flower to flower, seeking the nectar of each; while the *Cinnyridæ* and *Trochilidæ* make no use whatever of the foot as they extract their food, but during the process of feeding are poised entirely on the wing. The two last-mentioned families, he adds, again approach each other in the slenderness of their bill, the vividness and changeable lustre of their plumage, and the habit of hovering on the wing when they feed. They are chiefly separated by the comparatively stronger foot and bill of the *Cinnyridæ;* but the geographical distribution of the two families points out a line of demarcation. Mr. Vigors concludes this part of his observations by acknowledging that these two typical families are the only groups in the tribe of whose situation he can speak with any confidence; and these two families form the subject of this article. ('Natural Affinities that connect the Orders and Families of Birds,' in 'Linn. Trans.,' vol. xiv.)

Mr. Swainson considers the *Cinnyridæ*, or Sun-Birds—so called by the natives of Asia in allusion to their splendid and shining plumage—the subtypical family of the *Tenuirostres*. He observes that the affinity is obvious between this family and the *Meliphagidæ;* but whether the direct passage is made by the short-billed Honey-Suckers (*Dicæum*, Cuv.) or by the Spider-Suckers (*Arachnothera*, Temm.) is uncertain. "The plumage of the meliphagous birds of Australia," says Mr. Swainson, "is almost universally dull, or at least destitute of those gay and beautiful tints which are so strikingly developed in the sun-birds: a rich golden-green, varied on the under parts with steel-blue, purple, bright-orange, or vivid-crimson, decorates nearly all the species, and produces a brillancy of colours only rivalled by those of the humming-birds. The bill is very long, slender, and acutely pointed, the margins being dentated in the most regular and delicate manner: yet these teeth are so small as scarcely to be seen by the naked eye; the tongue is formed into a bifid tube, or rather, as we suspect, into two flattened filaments; thus differing materially from that of the honey-suckers, which always ends in a brush: the bill also is never notched. The difference between the two structures is softened down by the intervention of the nectar-birds (*Nectarinia*, Ill.), whose bill shows a union of both characters, the margins being finely dentated, and the tip distinctly notched. The species of the latter are few; and while *Cinnyris* is restricted to the tropics of the Old World, *Nectarinia* represents them in the New. Some few other forms, found in Australia and in the Oceanic Islands, belong to this group, and they are arranged in the genera *Melithreptes* and *Dicæum*, but their habits are imperfectly understood."

The genera arranged by Mr. Swainson under the family *Cinnyridæ* are *Melithreptes*, *Cinnyris*, *Anthreptes*, *Nectarinia*, and *Dicæum*. The family stands between the *Meliphagidæ* and the *Trochilidæ*.

Mr. G. R. Gray makes the *Nectarinidæ*, as he writes the word, the second family of the tribe *Tenuirostres*, placing it between the *Upupidæ* and the *Trochilidæ*.

The *Nectarinidæ*, in his arrangement, comprise the following sub-families and genera :—

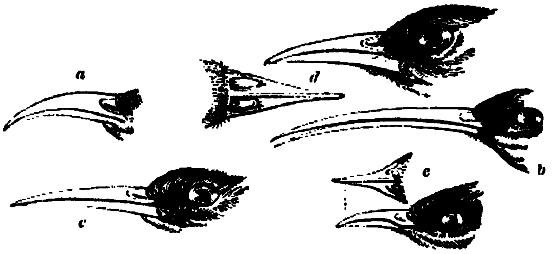
Sub-Family 1. *Nectarininæ*.

Genera :—*Moho*, Less. (*Merops*, *Certhia*, Gm.; *Gracula*, Merr.; *Meliphaga*, Temm.). *Drepanis*, Temm. (*Certhia*, Gm.; *Melithreptus*, Vieill.; *Vestiaria*, Flem.). *Arachnothera*, Temm. (*Cinnyris*, Horsf.; *Certhia*, Lath.). *Nectarinia*, Ill. (*Certhia*, Linn.; *Mellisuga*, Vieill.; *Cinnyris*, Cuv.; *Rhundace*, Mœhr.). *Ptiloturus*, Sw. (*Promerops*, Less.; *Upupa*, Gm.). *Anthreptes*, Sw. (*Mellisuga*, Vieill.; *Cinnyris*, Sw.). *Certhionyx*, Less. (*Certhia*, Cuv.). *Dicæum*, Cuv. (*Certhia*, Gm.).

Sub-Family 2. *Cærebinæ*.

Certhiola, Sundev. (*Furnarius*, Steph.; *Nectarinia* (Ill.), Less.; *Certhia*, Linn.). *Dacnis*, Cuv. (*Certhia*, Linn.). *Uncirostrum*, Lafr. and D'Orb.

Upon the whole we take the arrangement of Mr. Swainson. The following cut is after his figures in the 'Classification of Birds.'



Bills of *Cinnyridæ*.

a, *Melithreptes*; *b*, *Cinnyris*; *c*, *Anthreptes*; *d*, *Nectarinia*; *e*, *Dicæum*.

The *Cinnyridæ* have the following characters :—Wings with the outermost quills more or less shortened or graduated. Bill more or less curved, generally entire. Nostrils short, oval, membranaceous, opening by a lateral slit. Feet moderate. Bill entire. (Sw.)

Melithreptes, Vieill.—Bill long, sickle-shaped; the sides considerably compressed; the culmen elevated, and the tips entire. Nostrils very short, opening by a semicircular slit. Tongue long; the tip only terminated by a bunch of short filaments. Wings moderate; the first three quills nearly equal. Feet robust, long; lateral toes equal; tarsus almost twice as long as the hind toe. Pacific Islands. (Sw.)

Example, *Melithreptes Pacifica*.

Cinnyris, Cuv.—Bill long, slender; the tips very acute and entire; the margins minutely denticulated; base of the upper madible folding over, and partly concealing that of the lower. Nostrils short, oval. Tongue retractile, simply forked; First quill spurious, second shorter than the third. Tail even or rounded. India and Africa. (Sw.)

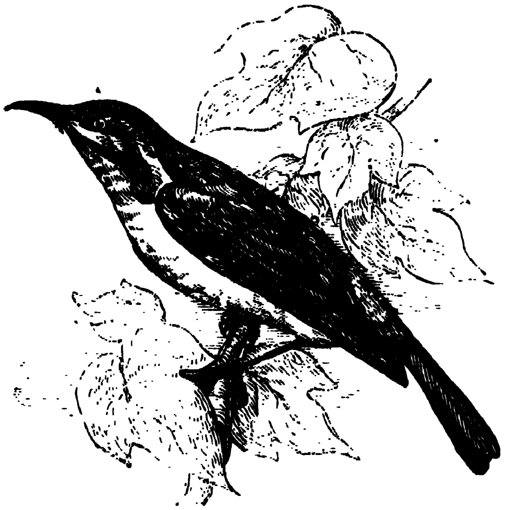
C. chalybeia. It is golden-green, with brown wings and tail, and narrow pectoral red band bordered above by another of steel-blue; upper tail-covers blue. This, according to Mr. Swainson, is *Certhia chalybeia*, Linn., Gmel.; Le Soui-manga à Collier, Vieill.; and Collared Creeper, Lath.

Lesser Collared Creeper (*Cinnyris chalybeia*). (Sw., 'Zool. Ill.')

Mr. Swainson remarks that another bird very nearly resembling this has been figured by Le Vaillant under the name of Le Sucrier à Plastron Rouge ('Ois d'Afr.,' pl. 300), but that Le Vaillant's reasons for separating them are, he thinks, sufficient, at least until more forcible ones are adduced than mere conjecture.

Anthreptes, Sw.—Bill moderate, rather strong, slightly curved; widening towards the base, which is much broader than it is high. Base of the under mandible thickened, and not partially covered by the upper. Wings, feet, and tail as in *Cinnyris*. (Sw.)

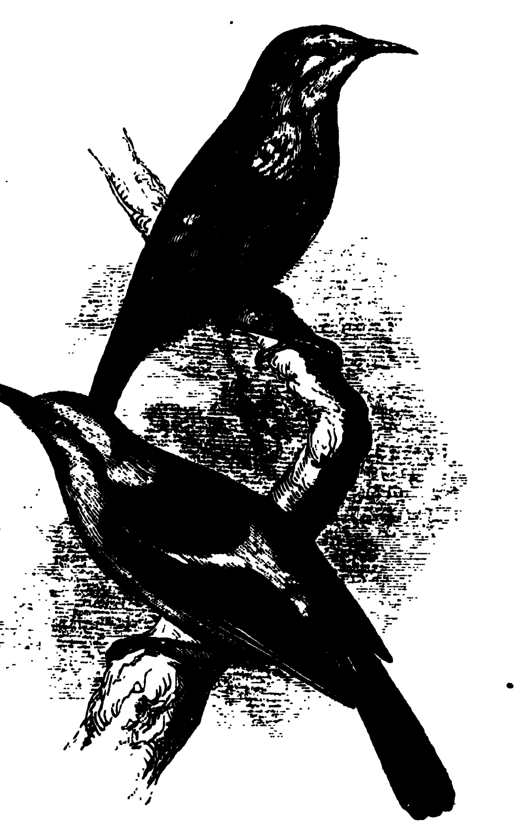
A. Javanica (***Nectarinia Javanica***, Horsf.). It is glossy metallic-purple above, olive-yellow beneath; scapulars, rump, and rather broad lateral stripe extending from the corner of the bill to the breast with a slight curvature, glossy violet; the throat chestnut; tail black.



Anthreptes Javanica. (Sw., 'Zool. Ill.')

Mr. Swainson describes this bird as a *Cinnyris* in the 'Zoological Illustrations,' and by the name here adopted in his 'Classification of Birds.' These changes however leave his declaration that it is not a *Nectarinia* (a genus confined to the New World) untouched.

Nectarinia, Ill.—Bill in general shorter than the head, wide at the base, compressed from the nostrils. Tip of the upper mandible with a distinct notch; the margins entire. Wings long; the first three quills nearly equal. Lateral toes unequal. South America only. (Swainson.)



Blue-Headed Warbler (*Nectarinia cyanocephala*). (Sw., 'Zool. Ill.')
Upper figure, female; lower figure, male.

N. cyanocephala. Male: Changeable blue; throat, back, tail, and wings black; the quills edged with blue. Female: green; head, cheeks, and scapulars bluish; throat gray. (Sw.)

This, according to Mr. Swainson, is (Male) *Motacilla Cayana*, Linn., Gmel.; *Sylvia Cayana*, Lath.; Pepit Bleu de Cayenne (?), Briss.; Cayenne Warbler, Lath.; and *Sylvia Cayenensis cærulea*, Briss. (Female) *Motacilla cyanocephala*, Gmel.; *Sylvia cyanocephala*, Gmel.; *Sylvia viridis*, and Le Pepit Verd, Briss.; Blue-Headed Warbler, and Blue-Headed Creeper (?), Lath.

Mr. Swainson states that the habits of this bird are perfectly the same as those of the rest of the *Nectariniæ*. "It is," he says, "one of the commonest birds of Brazil, and appears spread over the whole extent of that country. It frequents the same trees as the humming-birds, hopping from flower to flower and extracting the nectar from each; but this is not done on the wing, because its formation is obviously different from the humming-birds, which, on the contrary, poise themselves in the air during feeding."

Mr. Swainson remarks that the young males, as usual before moulting, have the colours of the female, and that the rich sky-blue of the male in some lights becomes greenish, and in others dark blue.

Dicæum, Cuv.—Bill short, remarkably broad at the base, and suddenly compressed beyond; the tips entire; the margins minutely denticulated; nostrils triangular. Wings, feet, and tail as in *Nectarinia*. Indian and Australian islands. (Sw.)

The figure referred to by Cuvier, and copied into the article CERTHIADÆ, is evidently a Humming-Bird, and must have been given by mistake. The reader will find a most elegant and characteristic drawing of *D. hirundinaceum* in Mr. Gould's grand work on the 'Birds of Australia.'

Mr. Gould states that the Swallow *Dicæum* has neither the habits of the Pardalotes nor of the Honey-Eaters: it differs, he says, from the former in its quick darting flight, and from the latter in its less prying, clinging, and creeping actions among the leaves, &c. "When perched on a branch," continues Mr. Gould, "it sits more upright, and is more swallow-like in its contour than either of the forms alluded to. The structure of its nest and the mode of its nidification are also very dissimilar. Its song is a very animated and long-continued strain, but is uttered so inwardly that it is almost necessary to stand beneath the tree upon which the bird is perched before its notes can be heard. Its beautiful purse-like nest is composed of the white cotton-like substance found in the seed-vessels of many plants; and among other trees is sometimes appended on a small branch of a *Casuarina* or an *Acacia pendula*. It was on the latter tree that I found a nest containing three or four young: a second nest with the eggs was given to me in Sydney. The ground-colour of the eggs is dull white, with very minute spots of brown scattered over the surface; they are 9 lines long by 5¼ lines broad. The male has the head, all the upper surface, wings, and tail black; throat, breast, and under tail-coverts scarlet; flanks dusky; abdomen white, with a broad patch of black down the centre; irides dark brown; bill blackish-brown; feet dark-brown. The female is dull-black above, glossed with steel-blue on the wings and tail; throat and centre of the abdomen buff; flanks light-brown; under tail-coverts a pale scarlet." Locality, the Australian continent generally.

CINNYRIS. [CINNYRIDÆ.]

CINQUEFOIL. [POTENTILLA.]

CI'ONUS, a genus of Coleopterus Insects of the section *Rhyncophora* and family *Curculionidæ*.

Schönherr (in his 'Synonymia Insectorum') links the present genus with the genera *Gymnætron*, *Mecinus*, and *Nanodes*, under the head *Cionides*, which may be considered as a sub-family. We shall therefore briefly state the characters of these genera under this head, first observing that the *Cionides* may be distinguished from allied groups by their having the antennæ 9- or 10-jointed, 5 of which always compose the funiculus, or that portion between the basal joint and the club which terminates the antenna.

The characters of the genus *Cionus* are as follows:—Antennæ short, the two basal joints of the funiculus obconical, the remainder short and truncated at the apex: the club long and indistinctly jointed. Rostrum elongate, curved, inserted in a groove beneath the thorax. Thorax small; elytra nearly spherical, furnished with tufts of a velvet-like nature; femora very thick in the middle; tibiæ simple, truncated at the apex.

Four species of this genus are found in England; they live both in their larva and imago states upon plants, more especially those of the genera *Scrophularia* and *Verbascum*.

Cionus Verbasci is about one-sixth of an inch in length and of a deep ash-colour approaching to black. The thorax is furnished on each side with a buff-coloured patch; the elytra have four longitudinal velvet-like bands, which are black, and interrupted with gray spots; there are two velvet-black spots on the suture, one near the base of the elytra and another near the apex; the former has a yellow spot joining it posteriorly, and the latter has a spot of the same colour before and behind.

These little insects are almost spherical. When touched or approached they apply their long proboscis close to the under side of the body (where there is a groove for its reception) and also the legs, and allow themselves to roll to the ground. Their larvæ, which are of a yellowish colour, and resemble small oblong masses of jelly, may be seen in the month of August on the leaves of the *Verbascum Thapsus* and some few other plants which they feed upon. When about to assume the pupa state they inclose themselves in a little brown spherical cocoon (less than an ordinarily sized pea) formed of a glutinous substance, which is attached to the leaves of a plant; in about a week or ten days after this the perfect insect makes its appearance.

The genus *Gymnætron* differs chiefly from *Cionus* in having the elytra somewhat ovate, sometimes depressed, and not covering the apex of the abdomen; and the anterior tibiæ furnished with a minute hook at the apex. *Gymnætron Beccabungæ* is the only species found in this country.

Mecinus may be distinguished from either of the two last-mentioned by the rostrum being short and thick; the thorax sub-cylindrical, the elytra elongate, nearly cylindrical, and covering the body; the tibiæ are armed with a hook at the apex. Three species of this genus are found in England. *M. semicylindricus* is about one-eighth of an inch in length, and of a blackish colour with ash-coloured pubescence.

The genus *Nanodes* has the antennæ rather long, the club large; rostrum elongate, slightly bent; thorax conical; elytra sub-ovate and humped; the anterior tibiæ unarmed. No species of this genus have yet been found in this country.

(Schönherr, *Synonymia Insectorum,—Genera et Species Curculionidum.*)

CIPOLIN. [MARBLE.]

CIRCÆA, a genus of Plants belonging to the natural order *Onagraceæ*. The species are found in woods and shady places. They have little whitish pink flowers, having a tubular superior calyx with a 2-parted limb, 2 petals, 2 stamens, and an ovary with 2 cells, each of which contains 1 erect ovule. The genus constitutes the type of a section of *Onagraceæ* in a reduced state. The species are commonly called Enchanter's Nightshade; but whatever supposed properties may have given rise to this name are purely imaginary.

C. Lutetiana has ovate leaves, subterete petioles, no bracteoles, petals deeply emarginate, calyx hairy, ovary 2-celled, fruit broadly obovate. It is found in woods and hedge-banks throughout Great Britain, though not an abundant plant.

C. alpina has ovate leaves, flat petioles and setaceous bracteoles, a glabrous calyx, and 1-celled ovary. It inhabits woods and thickets in mountainous districts, and is a rarer plant than the last.

CIRCÆTUS. [FALCONIDÆ.]

CIRCULATION OF THE BLOOD. As the blood is necessary for the nutrition of all the tissues of the body and for the development of the actions of its organs [BLOOD], it must be put in motion in order to be borne to them. "In man and in all the higher animals an apparatus is provided, partly for the purpose of originating an impelling force to put the blood in motion, and partly for the purpose of conveying the blood when put in motion to the different parts of the body."

The organ that puts the blood in motion is the heart; the pipes or conduits which distribute the blood to the different parts of the body are the great vessels in connection with the heart. The course of the circulation, which in all the higher animals is double--namely, one through the lungs, called therefore the Pulmonic, or the Lesser Circulation; the other through the system, called therefore the Systemic, or the Greater Circulation—will be best understood by an examination of the heart and vascular apparatus by which the circulation is carried on. [HEART.] In this place therefore it will be sufficient to refer to the evidence by which it is proved that the blood is really in motion. Dr. Southwood Smith, in his popular work on the 'Philosophy of Health,' thus sums up the proofs that the blood is a flowing stream, and that it constantly pursues a regular and determinate course.

"1. With the microscope, in the transparent parts of animals, the blood can be seen in motion; and if its course be attentively observed, its route may be clearly traced.

"2. The membranes termed valves are so placed as to allow of the freest passage to the blood in the circle described; while they either altogether prevent, or exceedingly impede its movements in any other direction.

"3. The effect of a ligature placed around a vein and an artery, and of a puncture made above the ligature in the one vessel and below it in the other, demonstrates both the motion of the blood and the course of it. When a ligature is placed round a vein, that part of the vessel which is most distant from the heart becomes full and turgid, on account of the accumulation of blood in it; while the part of the vessel which is between the ligature and the heart becomes empty and flaccid, because it has carried on its contents to the heart and it can receive no fresh supply from the body. When, on the contrary, a ligature is placed round an artery, that portion of the vessel which lies between the ligature and the heart becomes full and turgid, and the other portion empty and flaccid. This can only be because the contents of the two vessels move in opposite directions—from the heart to the artery, from the artery to the vein, and from the vein to the heart. At the same time, if the vein be punctured above the ligature, there will be little or no loss of blood; while if it be punctured below the ligature, the blood will continue to flow until the loss of it occasions death; which could not be unless the blood were in motion, nor unless the direction of its course were from the artery to the vein, and from the vein to the heart.

"4. If fluids be injected into the veins or arteries, whether of the dead or the living body, they readily make their way and fill the vessels, if thrown in the direction stated to be the natural course of the circulation; but they are strongly resisted if forced in the opposite direction."

The author concludes his account of the structure of the heart and blood-vessels, and of the course which the stream of blood is ascertained constantly to pursue, with the following reflections:—

"Such is the description, and, with the exception of the first proof, such the evidence of the circulation of the blood in the human body, pretty much as it was given by the discoverer of it, the illustrious Harvey. Before the time of Harvey, a vague and indistinct conception that the blood was not without motion in the body had been formed by several anatomists. It is analogous to the ordinary mode by which the human mind arrives at discovery (chap. iii., p. 103), that many minds should have an imperfect perception of an unknown truth before some one mind sees it in its completeness, and fully discloses it. Having about the year 1620 succeeded in completely tracing the circle in which the blood moves, and having at that time collected all the evidence of the fact, with a rare degree of philosophical forbearance, Harvey still spent no less than eight years in re-examining the subject and in maturing the proof of every point, before he ventured to speak of it in public. The brief tract which at length he published was written with extreme simplicity, clearness, and perspicuity, and has been justly characterised as one of the most admirable examples of a series of arguments deduced from observation and experiment that ever appeared on any subject.

"Contemporaries are seldom grateful to discoverers. More than one instance is on record, in which a man has injured his fortune and lost his happiness through the elucidation and establishment of a truth which has given him immortality. It may be that there are physical truths yet to be brought to light, to say nothing of new applications of old truths, which, if they could be announced and demonstrated to day, would be the ruin of the discoverer. It is certain that there are moral truths to be discovered, expounded, and enforced, which, if any man had now penetration enough to see them, and courage enough to express them, would cause him to be regarded by the present generation with horror and detestation. Perhaps during those eight years of re-examination the discoverer of the circulation sometimes endeavoured in imagination to trace the effect which the stupendous fact at the knowledge of which he had arrived would have on the progress of his favourite science; and, it may be, the hope and the expectation occasionally arose, that the inestimable benefit he was about to confer upon his fellow men would secure to him some portion of their esteem and confidence. What must have been his disappointment when he found, after the publication of his tract, that the little practice he had had as a physician by degrees fell off? He was too speculative, too theoretical, not practical. Such was the view taken even by his friends. His enemies saw in his tract nothing but indications of a presumptuous mind, that dared to call in question the revered authority of the ancients; and some of them saw, moreover, indications of a malignant mind, that conceived and defended doctrines which, if not checked, would undermine the very foundations of morality and religion. When the evidence of the truth became irresistible, then these persons suddenly turned round and said that it was all known before, and that the sole merit of this vaunted discoverer consisted in having circulated the circulation. The pun was not fatal to the future fame of this truly great man, nor even to the gradual though slow return of the public confidence even during his own time, for he lived to attain the summit of reputation."

For an account of the circulating apparatus, see the articles ARTERY, CAPILLARY VESSELS, BLOOD VESSELS, HEART, VEIN. The nature of the circulating fluid is given under BLOOD. For the history of the discovery of the circulation by Harvey, see the article HARVEY, WILLIAM, in the HIST. AND BIOG. DIV.

CIRCUS. [FALCONIDÆ.]

CIRL BUNTING. [EMBERIZA.]

CIRRHIBA'RBA, a genus of Fishes of the family *Gobiodæ* and section *Acanthopterygii*. Only one species of this genus is yet discovered, and this is from India. It has a tentaculum over each eye and nostril, three large tentacula at the end of the muzzle, and eight under the point of the lower jaw. These tentacula constitute the chief distinction between this genus and that of *Clinus*, to which it is closely allied.

CIRRHIGRADA. [ACALEPHÆ.]

CIRRHINUS. [GOBIO.]

CIRRHOBRANCHIATA. [DENTALIUM.]

CIRRHUS. [TENDRIL.]

CIRRI'PEDIA, or CIRRHIPEDA (*Lepas* of Linnæus, *Cirrhopodes* of Cuvier and Férussac, Cirrhipèdes of Lamarck, *Nematopodes* of De Blainville, Cirripèdes of Latreille), a well-defined natural group of Marine Invertebrate Animals, whose place in the system has occasioned much doubt and difference of opinion among zoologists. In the earlier times the most absurd stories were propagated and believed in relation to one of the most common genera, *Pentalasmis anatifera*

(*Lepas anatifera* of Linnæus), the Common or Duck Barnacle. To the references on this head in the article BERNICLE-GOOSE, we may add the testimony of Sir Robert Moray to show how long the delusion lasted, and in what positive terms a witness can state the thing that is not. "In every shell that I opened I found a perfect sea-fowl; the little bill like that of a goose, the eyes marked, the head, neck, breast, wings, tail, and feet formed, the feathers everywhere perfectly shaped, and blackish-coloured, and the feet like those of other water-fowl, to my best remembrance." So widely spread has been this delusion, that it is stated that the Roman Catholics are permitted, in France at least, to eat the Bernicle-Goose upon fast days and during the whole of Lent, in consequence of its supposed marine origin.

Organisation, and place in the Natural System.—Linnæus placed the *Cirripedia*, with the generic name of *Lepas*, among the Multivalves of his *Vermes* (*Testacea*), between *Chiton* and *Pholas*; and, supposing that the form existed without a shell, found a situation for it under the name of *Triton*, between *Terebella* and *Lernæa*. Cuvier, in the first and also in the last edition of the 'Règne Animal,' says that the existence of these Tritons is not confirmed, and that we must suppose that Linnæus had only seen the animal of an *Anatifa* (*Pentalasmis*), which had been taken out of its shell. Rang, however, thinks that he has found the Linnæan genus *Triton* in certain specimens brought home by Messrs. Lesson and Garnot, Quoy and Gaimard, and has published it under the name of *Alepas*. Bruguières divided the genus *Lepas* into two; the first, *Anatifa*, a barbarous word for *Anatifera* (the Anatifes of the French), comprising the Pedunculated Cirripedes; and the second, *Balanus*, the Sessile species. Cuvier, under the name of *Cirrhopoda*, made these animals the sixth class of his Mollusks, which he places between the *Brachiopoda* and the first class (Annélides) of his third great division of the animal kingdom, namely, the Articulated Animals, and in the 'Règne Animal' they appear between *Orbicula* and *Serpula*. Lamarck, under the name of *Cirrhipeda*, his tenth class of Invertebrate Animals, arranges them between the sedentary *Annelides* and his *Conchifera*, dividing them into two orders: 1st, the Sessile Cirripedes; 2nd, the Pedunculated Cirripedes. In his system they stand between *Magilus* and *Aspergillum*. Latreille, though he does not disturb this arrangement, evidently considers them as related to the *Ostracoda*, among the Branchiopodous Crustaceans. He says that the Sessile Cirripedes seem to represent the animals which terminate the Acéphales Enfermés of Cuvier. He observes that the two tubular processes of *Otion* represent the two tubes of some of the *Acephala*, though with different uses, the tentacula being converted into jaws. The cirri he considers as a kind of feet analagous to the sub-abdominal appendages of many Crustaceans, especially those of the *Amphipoda*, and is of opinion that we may also compare them to those of many Annelides. The oviduct, he remarks, has some resemblance to that of *Phalangium*. Finally, he expresses a conjecture, that nature, to form the Cirripedes, has borrowed different organs from animals of several classes. Mr. William Sharp M'Leay, in his profound and philosophical work, 'Horæ Entomologicæ,' considers that *Pentalasmis* exhibits the greatest affinity with the *Ostracoda*; but he seems to be of opinion that there exists an affinity between the shell of *Balanus* and that of *Echinus*, and sanctions Latreille's opinion that the articulated cirri have their analogues in the arms of the *Radiata*, particularly of *Comatula*. Dr. Leach, who has described several genera unnoticed till his time, divided the class into two orders: 1st, *Campylosomata*, comprising the Pedunculated section; and 2nd, *Acamptosomata*, including the Sessile species. M. de Blainville makes the Cirripedes the first class (*Nematopoda*) of his sub-type *Malentozoaria*, a group which corresponds to the Multivalves of Linnæus, after separating from them the genus *Pholas*, so that De Blainville's *Malentozoaria* consist of the Cirripedes and Chitons. The Cirripedes, he thinks, have an evident relation to the Bivalve Mollusks, by means of their calcareous envelope, in which he recognises the pieces of the shell of the *Pholades*, and even the analogue of the tube of the neighbouring genera. He also considers the relationship further indicated by the recurved position of the animal fixed head downwards (la tête en bas); but he also considers that their relations to certain animals of the type *Entomozoaria* are numerous, by means of the horny, locomotive, articulated appendages which are branchial, at least at the root, becoming, towards the mouth, true horny denticulated jaws. Mr. Thompson, in his 'Zoological Researches,' considers the Cirripedes to be true *Crustacea*, and that in the first state of these animals they not only possess perfect freedom and power of motion, but organs of sight. On the 28th April 1823, Mr. Thompson states that he took in a small muslin towing-net while crossing the ferry at Passage, among other minute creatures, a small translucent animal, one-tenth of an inch long, of a somewhat elliptical form, but very slightly compressed laterally, and of a brownish tint. When in a state of perfect repose it resembled a very minute mussel, and lay upon one of its sides at the bottom of the vessel of sea-water in which it was placed; at this time all the members of the animal were withdrawn within the shell, which appeared to be composed of two valves, united by a hinge along the upper part of the back, and capable of opening from one end to the other along the front, to give occasional exit to the limbs. These were of two descriptions, namely, anteriorly a large and very strong pair, provided with a cup-like sucker and hooks, serving solely to attach the animal to rocks, stones, &c.; and, posteriorly, six pairs of natatory members, so articulated as to act in concert, and to give a very forcible stroke to the water, causing the animal, when swimming, to advance by a succession of bounds after the same manner as the Water-Flea (*Daphnia*) and other *Monoculi*, but particularly *Cyclops*, whose swimming-feet are extremely analogous. [BRANCHIOPODA.] The tail, usually bent up under the belly, is extremely short, composed of two joints, and terminating in four setæ, and is employed to assist in progression and in changing the position from a state of repose. The greatest peculiarity however in the structure is in the eyes, which, although constantly shielded by the valves of the shell, are pedunculated as in the Crab and Lobster, and placed entirely at the sides of the body. Mr. Thompson observes that this animal, but for its pair of pedunculated eyes, would find a place as a new genus of *Ostracoda*; that its members approximate it to *Argulus* on the one hand and to *Cyclops* on the other—genera which are widely separated; while the eyes show its relationship to the *Decapoda* (crabs, lobsters, &c.) The individuals presented no variation indicative of a difference of sex; and this, with their anomalous organisation, induced a belief that they were the larvæ or disguised states of some crustaceous animal, or (as it had been previously ascertained that the Cirripedes were *Crustacea*) that they were the males of these, Mr. Thompson not being disposed to believe that the two sexes were united in the same individual. What follows being of the last importance, we give in the author's own words:—"Under the foregoing impressions, some of them were collected in the spring of 1826, and, in order to see what changes they might undergo, were kept in a glass vessel, covered by such a depth of sea-water that they could be examined at any time by means of a common magnifying-glass; they were taken May 1st, and on the night of the 8th the author had the satisfaction to find that two of them had thrown off their exuvia (exuviæ), and, wonderful to say, were firmly adhering to the bottom of the vessel, and changed to young barnacles, such as are usually seen intermixed with grown specimens on rocks and stones at this season of the year. (*Balanus pusillus*, Penn.) In this stage the sutures between the valves of the shell and of the operculum were visible, and the movements of the arms of the animal within, although these last were not yet completely developed; the eyes also were still perceptible, although the principal part of the colouring-matter appeared to have been thrown off with the exuvium (exuviæ). On the 10th another individual was seen in the act of throwing off its shell, and attaching itself as the others to the bottom of the glass. It only remains to add, that as the secretion of the calcareous matter goes on in the compartments destined for the valves of the shelly covering, the eyes gradually disappear, from the increasing opacity thence produced, and the visual ray is extinguished for the remainder of the animal's life; the arms at the same time acquire their usual ciliated appearance. Thus, then, an animal originally natatory and locomotive, and provided with a distinct organ of sight, becomes permanently and immoveably fixed, and its optical apparatus obliterated, and furnishes not only a new and important physiological fact, but is the only instance in nature of so extraordinary a metamorphosis."

"During the whole of the spring and summer months," says Mr. Thompson, "the water teems with these exuvia (exuviæ) of *Tritones* (the animal inhabitant, according to Linnæus, of the barnacles): it is impossible to avoid drawing up numbers every time a towing-net is thrown out, nay the tide is at times discoloured from their abundance; but to be certain that these are really such, let a stone with several barnacles upon it be kept in sea-water, regularly renewed, towards the latter end of April or the beginning of May, and with due attention many of them may be observed in the act of throwing off exuvia (exuviæ) in every respect identical; let it be recollected, however, that these are the casts of the animal alone, and not of the valves of the shell or of the operculum." Mr. G. B. Sowerby ('Genera of Shells,' '*Scalpellum*') thus writes on the subject of Mr. Thompson's discovery:—"Without describing the facts, or entering upon the arguments with which he supports this opinion" (that is, that the *Cirripedia* are *Crustacea*), "we must be permitted to say that we do not think that he has fully demonstrated it; at the same time, considering that, as far as we hitherto knew, the Cirripedes were all attached, the circumstance of their being free when very young accounts well to our mind for the fact of each species being found attached to peculiar situations, which would only be compatible with the notion of their being at one time free agents, and possessed of an instinctive volition determining their choice of situation." Professor Owen, in the 'Catalogue of the Museum of the College of Surgeons' ('Cirripeda'), speaks of the discovery without expressing any doubt.

But Mr. Thompson has since, in a paper read before the Royal Society on the 5th of March 1835, declared his "discovery of the metamorphosis in the second type of the Cirripedes, namely, the *Lepades*, completing the natural history of these singular animals, and confirming their affinity with the *Crustacea*;" and the Memoir, with a plate, is published in the second part of the 'Philosophical Transactions' for 1835. The following is the abstract of the paper:—"The discoveries made by the author of the remarkable metamorphoses which the animals composing the first family of the Cirripedes, or *Balani*, undergo in the progress of their development, and which he has published in the third number of his 'Zoological Researches,' (p. 76), are in the present paper, which is intended as a prize essay for one of the royal medals, followed up by the report of his discovery of similar changes exhibited by three species of two other genera of the second tribe of this family, namely, the *Lepades*. The larvæ of this tribe, like those of the *Balani*, have the external appearance of Bivalve Monoculi, furnished with locomotive organs, in the form of three pairs of members, the most anterior of which are simple, and the other bifid. The back of the animal is covered by an ample shield, terminating anteriorly in two extended horns, and posteriorly in a single elongated spinous process. Thus they possess considerable powers of locomotion, which, with the assistance of an organ of vision, enable them to seek their future permanent place of residence. The author is led from his researches to the conclusion that the Cirripedes do not constitute, as modern naturalists have considered them, a distinct class of animals, but that they occupy a place intermediate between the *Crustacea decapoda* (with which the *Balani* have a marked affinity) and the *Crustacea entomostraca*, to which the *Lepades* are allied; and that they have no natural affinity with the Testaceous *Mollusca*, as was supposed by Linnæus, and all the older systematic writers on zoology."

Mr. Thompson does not seem to have been aware of a paper by Dr. J. Martin-Saint-Ange, read at the Academy of Sciences on the 14th July 1834, and published in the 'Savans Etrangers' (tome vi.), and separately by Baillière (1835). The following is the summary of the principal facts stated by him in the course of a very laborious and acute investigation:—The mouth of the Pedunculated Cirripedes is composed of pieces entirely comparable to those of the mouths of many *Crustacea*, and especially of the *Phyllosomes;* the upper lip, the palpi, and the mandibles are so analogous that the resemblance extends even to the form. The three jaw-feet (pieds-mâchoires), which are met with most commonly in the *Crustacea*, are conjoined in a single jaw-foot which receives the nervous trunks; at its base are always found from two to four branchiæ. The ten ordinary feet of the *Crustacea* are faithfully represented in the Anatifes (*Campylosomata*); at the base of many among them are found branchiæ disposed like those of certain *Crustacea*, and the number even is sometimes repeated. There exists in each foot a double canal, fit for establishing a circulating current, and traversing all the articulations of the cirri. The body is composed of a certain number of rings, or of articulations, very distinct, each of which supports a pair of feet. In the interior of the body there are a dorsal vessel (like that in a great number of the Articulated Animals), and a double series of ganglions; of which the number, according to Dr. Martin-Saint-Ange's researches, is equal to that of the feet; there is besides another pair on the lateral parts of the stomach. The pedicle may be regarded as analogous to the tail of many *Crustacea*; it is in this cavity, and not, as has been said, on the back, that the eggs are found; these pass afterwards by a conduit, not yet indicated, in the envelope, which, by its resemblance to the mantle of the *Mollusca*, establishes the only possible analogy between the Cirripedes and the last-named animals. The organs placed upon the back, which Cuvier described as eggs, are the generative apparatus of the male, of which the disposition is very remarkable. Finally, the stomach and intestinal canal inclose in the interior a membranous sac of a retort-shape; the disposition and use of which establish, according to the researches of M. Serres, an additional approximation between the Cirripedes and the Annelides. Dr. Martin-Saint-Ange then proposes, as the last result of his labours, to place the class *Cirripedia* at the end of the *Crustacea*, so as to establish a natural link or passage between the superior Articulated Animals and the *Annelida*. Such are the conclusions drawn in the Memoir of Dr. Martin-Saint-Ange, who refers with approbation to the discoveries of Mr. Thompson, published in 1830; and before we proceed to give a further account of the structure of the *Cirripedia* we will state Mr. Thompson's view of the ovarial system. "In the whole of the tribe of the Cirripedes," observes Mr. Thompson, in his paper in the 'Philosophical Transactions' above quoted, "the ova, after expulsion from the ovarium, appear to be conveyed by the ovipositor into the cellular texture of the pedicle, just beneath the body of the animal, which they fill to the distance of about an inch. When first placed in this situation, they seem to be amorphous and inseparable from the pulpy substance in which they are imbedded; but as they approach to maturity they become of an oval shape, pointed at both ends, and are easily detached. Sir Everard Home has given a very good representation of them, at this stage of their progress, in his 'Lectures on Comparative Anatomy,' from the elegant pencil of Mr. Bauer. During the stay of the ova in the pedicle, they render this part more opaque and of a bluish tint; the ova themselves, and the cellular texture with which they are surrounded, being of a pale or azure-blue colour. It is difficult to conceive in what manner the ova are extricated from the situation above indicated; but it is certainly not by the means suggested by Sir Everard Home in the above-mentioned lecture, namely, by piercing outwards through the membranes of the pedicle, for the ova are subsequently found forming a pair of leaf-like expansions, placed between either side of the body of the animal and the lining membrane of the shells in *Lepas* (*Pentalasmis*), or of the leathery internal tunic in *Cineras*. These leaves have each a separate attachment at the sides of the animal to the septum, which divides the cavity occupied by the animal from that of the pedicle; they are at first comparatively small, have a rounded outline, and possess the same bluish colour which the ova had in the pedicle; but as the ova advance in progress these leaves extend in every dimension, and lap over each other on the back, passing through various lighter shades of colour into pale-pink, and finally, when ready to hatch, become nearly white. These leaves appear to be composed of a layer of ova irregularly placed, and imbedded in a kind of parenchymatous texture, out of which they readily fall when about to hatch, on its substance being torn asunder; indeed, it appears at length to become so tender as to fall entirely away, so that after the period of gestation is past no vestige of these leafy conceptacles is to be found. When the larvæ, barely visible to the naked eye, burst forth from the ova, their development goes on with such rapidity that they seem to grow sensibly while under observation. The larva of the *Lepades* then is a tailed *Monoculus*, with three pairs of members, the most anterior of which are simple, the others bifid, having its back covered with an ample shield, terminating anteriorly in two extended horns, and posteriorly in a single elongated spinous process."

The following observations on the development of the larvæ of these animals, by Mr. Darwin, are amongst the latest contributions to this interesting inquiry:—"The ova, and consequently the larvæ of the *Lepadidæ*, in the first stage, whilst within the sac of the parent, vary in length from ·007 to ·009 in *Lepas*, to ·023 of an inch in *Scalpellum*. My chief examination of these larvæ has been confined to those of *Scalpellum vulgare;* but I saw them in all the other genera. The larva is somewhat depressed, but nearly globular; the carapace anteriorly is truncated with lateral horns; the sternal surface is flat and broad, and formed of thinner membranes than the dorsal. The horns just alluded to are long in *Lepas* and short in *Scalpellum;* their ends are either rounded and excessively transparent, or, as in *Ibla*, furnished with an abrupt minute sharp point. Within these horns I distinctly saw a long filiformed organ, bearing excessively fine hairs in lines, so exactly like the long plumose spines on the prehensile antennæ of the larvæ in the last stage, that I have not the least doubt that these horns are the cases in which antennæ are in process of formation. Posteriorly to them on the sternal surface, near each other, there are two other minute doubly-curved pointed horns, about ·004 in length, directed posteriorly; and within these I again saw a most delicate articulated filiformed organ and a thicker pedicle. In an excellent drawing by Mr. C. S. Bate, of the larvæ of a *Chthamalus* (*Balanus punctatus* of British authors), after having been kept alive and moulted once, these organs are distinctly shown as articulated antennæ (without a case), directed forwards: hence, before the first moult in *Scalpellum* we have two pairs of antennæ in process of formation. Anteriorly to the bases of these smaller antennæ is seated the heart-shaped eye (as I believe it to be), ·001 of an inch in diameter, with apparently a single lens, surrounded, except at the apex, by dark-reddish pigment-cells. In some cases, as in some species of *Lepas*, the larvæ, when first excluded from the egg, have not an eye, or a very imperfect one. There are three pairs of limbs, seated close together in a longitudinal line, but some way apart in a transverse direction. The first pair always consists of a single spinose ramus; it is not articulated in *Scalpellum*, but is multi-articulate in some genera; it is directed forwards. The other two pairs have each two rami, supported on a common haunch or pedicle; in both pairs the longer ramus is multi-articulate, and the shorter ramus is without articulations, or with only traces of them; the longer spines borne on these limbs (at least in *Scalpellum* and *Chthamalus*) are finely plumose. The abdomen terminates a little beyond the posterior end of the carapace in a slightly upturned horny point. A short distance anteriorly to this point, a strong spinose forked projection depends from the abdominal surface. Messrs. V. Thompson, Goodsir, and Bate have kept alive for several days the larvæ of *Lepas*, *Conchoderma*, *Balanus*, *Verruca*, and *Chthamalus*, and have described the changes which supervene between the first and third exuviations. The most conspicuous new character is the great elongation of the posterior point of the carapace into an almost filiform spinose point in *Lepas*, *Conchoderma*, *Chthamalus*, and *Balanus*, but not, according to Goodsir, in one of the species of the latter genus. The posterior point also of the abdomen becomes developed in *Balanus* (Goodsir) into two very long spear-like processes, serrated on their outer sides; in *Lepas* and *Conchoderma*, according to Thompson, into a single tapering spinose projection; and in *Chthamalus*, as figured by Mr. Bate, the posterior bifid point, as well as the depending ventral fork, increases much in size. Another important change, which has been particularly attended to by Mr. Bate, is the appearance of spinose projections and spines (some of which are thick, curved, and strongly plumose or almost pectinated along their inner sides) on the pedicles and lower segments of the shorter rami of the two posterior pairs of limbs." In this stage of the growth of the larva, Mr. Darwin found the mouth in *Scalpellum vulgare* seated on a very slight prominence in a most remarkable situation, namely, in a central point between the bases of the three pairs of legs. Mr. Darwin continues:—"I traced by dissection the œsophagus for some little way, until lost in the cellular and oily matter filling the whole animal, and it was directed anteriorly, which is the direction that might have been expected from the course followed by the œsophagus in the larva in the last stage, and in the mature Cirripede."

The larva, in its second stage of development, is known only from a single specimen described and figured by Burmeister ('Beiträge zur Naturgeschichte der Rankenfüsser,' s. 16). In its general shape and compressed form it seems to come nearer the last than the first stage. It has only three pairs of legs, situated much more posteriorly on the body than in the first stage, and all directed posteriorly. They are much shorter than in their earlier stages. They are undoubtedly the three pairs of limbs of the first stage metamorphosed. The chief development of the larva since its first stage is towards its anterior end.

In the last stage the larvæ have increased many times in size since their exclusion from the egg. They are now much compressed, nearly of the shape of a *Cypris*, or mussel-shell, with the anterior end the thickest, the sternal surface nearly or quite straight, and the dorsal arched. Almost the whole of what is externally visible consists of the carapace, the thorax and limbs being hidden and inclosed by its backward prolongation, and even at the anterior end of the animal the narrow sternal surface can be drawn up, so as to be likewise inclosed. The antennæ are large and conspicuous. They are at first well-furnished with muscles, and serve as organs of locomotion, and apparently as feelers; but their main function is to attach the larva, preparatory to its final metamorphosis into a Cirripede. The disc can adhere even to so smooth a surface as a glass tumbler. The attachment is at first manifestly voluntary, but soon becomes involuntary and permanent. Mr. Darwin makes the following remarks upon the eyes and mouth in their last stage:—

"Eyes. The posterior and rounded margins of the basal articulation of the above-described prehensile antennæ are reflected inwards, in the form of two forked horny apodemes, together resembling two letters UU close together. These project up inside the animal for at least one-third of its thickness, from the sternal to the dorsal surface. The two great almost spherical eyes in *Lepas australis*, each $\frac{1}{150}$th of an inch in diameter, are attached to the outer arms, thus, • UU •, in the position of the two full stops. Hence the eyes are included within the carapace. Each eye consists of eight or ten lenses, varying in diameter in the same individual from $\frac{1}{2000}$th to $\frac{3}{2000}$th of an inch, inclosed in a common membranous bag or cornea, and thus attached to the outer apodemes. The lenses are surrounded half-way up by a layer of dark pigment cells. The nerve does not enter the bluntly-pointed basal end of the common eye, but on one side of the apodeme. The structure here described is exactly that found, according to Milne-Edwards, in certain *Crustacea*. In specimens just attached, in which no absorption has taken place, two long muscles with transverse striæ may be found attached to the knobbed tips of the two middle arms of the two • UU • and running up to the antero-dorsal surface of the carapace, where they are attached. Other muscles (without transverse striæ) are attached round the bases on both sides of both forks. The action of these muscles would inevitably move the eyes, but I suspect that their function may be to draw up the narrow deeply-folded sternal surface, and thus cause the retraction of the great prehensile antennæ within the carapace.

"Mouth. This is seated in exactly the same position as in the mature Cirripede, on a prominence fronting the thoracic limbs, and so far within the carapace that it was obviously quite unfitted for the seizure of prey; and it was equally obvious that the limbs were natatory, and incapable of carrying food to the mouth. This enigma was at once explained by an examination of the mouth, which was found to be in a rudimentary condition, and absolutely closed, so that there would be no use in prey being seized. Underneath this slightly-prominent and closed mouth I found all the masticatory organs of a Cirripede in an immature condition. The state of the mouth will be at once understood if we suppose very fluid matter to be poured over the protuberant mouth of a Cirripede, so as to run a little way down in the shape of internal crests, between the different parts, and in the shape of a short, shrivelled, certainly closed tube, a little way (·008 of an inch in *L. australis*) down the œsophagus. Hence the larva, in this, its last stage, cannot eat. It may be called a locomotive pupa; its whole organisation is apparently adapted for the one great end of finding a proper site for its attachment and final metamorphosis." In this stage the thorax is much compressed, the six pairs of legs are all close one behind the other. In all the limbs the obliquely-truncated summit of the terminal segment of the inner ramus bears three very long beautifully plumose spines; in the first pair the summit of the outer ramus bears four, and in the five succeeding pairs six similar spines. The abdomen is small, and consists of only three segments: it contains only the rectum, and two delicate muscles running into two appendages, between the bases of which the anus is situated.

Whilst the young *Lepas* is closely packed within the larva, the capitulum, or shell, about equals the length of the peduncle. Even at this early period the muscles of the peduncle are distinct. The compound eyes, which we have seen are attached to apodemes springing from the sternal surface of the larval carapace, are consequently cast off with it. Whilst the young Cirripede is packed within the larva, the outer integument of its peduncle necessarily forms a deep transverse fold passing over the eyes and apodemes. This determines the position and origin of the sac in the young Cirripede.

"The larva," says Mr. Darwin, "fixes itself with its sternal surface parallel and close to the surface of attachment, and the antennæ become cemented to it: if the Cirripede after its metamorphosis had remained in this position, the cirri could not have been exserted, or only against the surface of attachment; but there is a special provision that the young Cirripede shall assume its proper position at right angles to the position which it held whilst within the larva, namely, with its posterior end upwards. This is effected in a singular manner by the exuviation of the great compound eyes, which we have seen are fastened to the outer arms of the double • UU • like sternal apodemes. These, together with the eyes, stretch transversely across and internally far up into the body of the larva; and as the whole has to be rejected or moulted, the membrane of the peduncle of the young Cirripede has necessarily to be formed with a wide and deep inward fold extending transversely across it; this, when stretched open after the exuviation of the larval carapace and apodemes, necessarily causes the sternal side of the peduncle to be longer than the dorsal, and as a consequence gives to the young Cirripede its normal position, at right angles to that of the larva when first attached."

That the homologies of the larva of the Cirripedes are with the *Crustacea* has before been pointed out. Mr. Darwin says:—"In *Crustacea*, according to the ordinary view, there are twenty-one segments; of these I can recognise in the Cirripede, on evidence as good as can generally be obtained, all with the exception of the four terminal abdominal segments; these do not occur in any species known to me in any stage of its development. If that part of the larva, in front of the mouth, bearing the eyes, the prehensile antennæ, and in an earlier stage another pair of antennæ, be formed, as is admitted in all other *Crustacea*, of three segments, then beyond a doubt, from the absolute correspondence of every part, and even every coloured mark, the peduncle of the *Lepadidæ* is likewise thus formed. The peduncle being filled by the branching ovarian tubes is no objection to this view, for I am informed, on the high authority of Mr. J. D. Dana, that this is the case with the cephalo-thorax in some true Crustaceans; for instance, in *Sapphirina*. To proceed:—the mouth, formed of mandibles, maxillæ, and outer maxillæ, corresponds with the fourth, fifth, and sixth segments of the archetype Crustacean. Posteriorly to the mouth we come, in the larva, to a rather wide interspace, without any apparent articulation or organ; and then to the thorax, formed of six segments, bearing the six pairs of limbs, of which the first pair differs slightly from the others. The thorax is succeeded by three small segments differently shaped, with the posterior one alone bearing appendages. These segments I cannot doubt, from their appearance alone, and from their apparent function of steering the body, are abdominal segments. If this latter view be correct, the thoracic segments are the six posterior ones of the normal seven segments; and there must be two segments missing between the outer maxillæ and the first thoracic pair of legs, which latter, on this view, springs from the ninth segment. Now, in a very singular Cirripede named *Proteolepas*, the two missing segments are present, the mouth being actually succeeded by eight segments, and these by the three usual abdominal segments, every segment in the body being as distinct as in an Annelide; hence in *Proteolepas*, adding the three segments for the mouth and three for the carapace, we have altogether seventeen segments, which, as I have stated, is the full number ever observed in any Cirripede; the four missing ones being abdominal, and I presume the four terminal segments. That the cavity in which the thorax is lodged in the larva, and therefore in the mature Cirripede, is simply formed by the backward production of the carapace, does not require any discussion. The valves have no homological signification."

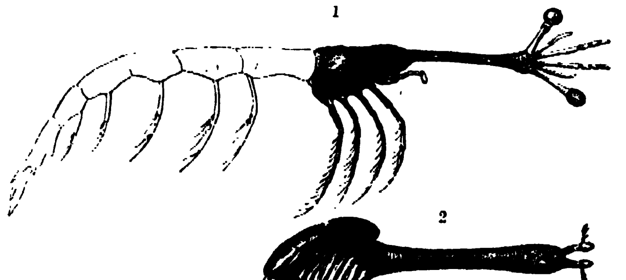


Fig. 1. A Stomapod Crustacean (*Leucifer*, V. Thompson.
Fig. 2. A species of *Lepas*.

The preceding wood-cut, copied from Darwin's work, will make these homologies clear. The upper figure is a Stomapod Crustacean (*Leucifer*, V. Thompson), and the abdomen, which becomes rudimentary in Cirripedes, is given in faint lines. The lower figure is a mature *Lepas* with the antennæ and eyes which are actually present in the larva, retained and supposed to have gone on growing. All that is seen of a Cirripede, whether pedunculated or sessile, is the three anterior segments of the head of a Crustacean, with its anterior end permanently cemented to a surface of attachment, and with its posterior end projecting vertically from it.

For the observation of the means by which these animals attach themselves after leading a free life we are also indebted to Mr. Darwin. In the larva, two ducts, called cement-ducts, can be traced from within the discs of the antennæ to the anterior or lower ends of the two gut-formed bodies, which are the incipient ovaries. These ducts are filled with an opaque cellular matter in the larva. In the mature Cirripedes, they can be followed in a slightly sinuous course along the muscles on each side within the peduncle, till they expand into two small organs, which Mr. Darwin calls cement-glands. These glands contain a strongly coherent pulpy opaque cellular mass, like that in the cement-ducts; but in some instances this cellular mass becomes converted, within either the ducts or gland, or within both, into a transparent tough yellow cement. Tubes are seen running into these glands, containing ova in every stage of development. From observations made on many species of Cirripedes, Mr. Darwin concludes that the gland itself is part of an ovarian tube specially modified; and further that the cellular matter, which in the ovarian tubes serves for the development of the ova, is, by the special action of the walls of the gland, changed into the opaque cellular matter in the ducts, and this again subsequently into that tissue or substance which cements the Cirripede to its surface of attachment. As the individuals grow and increase in size, so do the glands and cement-ducts; but it often happens that when a specimen is immoveably attached, the cement-apparatus ceases to act, and the cellular contents of the duct become converted into a thread of transparent cement. The cement removed from the outside of a Cirripede consists of a thin layer of very tough bright-brown transparent laminated substance, exhibiting no structure under the microscope. Its chemical reactions are those of Chitine. In the larva, the cement always escapes through the prehensile antennæ, and in most instances it continues to do this throughout the life of the animal. There are however exceptions, and in *Scalpellum vulgare*, and probably others which live attached to coral, the cement soon ceases to debouch from the antennæ, but instead bursts through a row of orifices on the rostral margin of the peduncle, by which means this margin is symmetrically fastened down to the delicate horny branches of the zoophyte.

The external shell, which misled early observers, and induced them to place the Cirripedes among the *Mollusca*, is called, in the *Lepadidæ*, the Capitulum. It is usually much flattened, but sometimes broadly oval in section. It is generally formed of five or more valves, connected together by very narrow or broad strips of membrane. When the valves are numerous, and they sometimes exceed a hundred in number, they are arranged in whorls, with each valve generally so placed as to cover the interval between the two valves above. The upper pair of valves, the peduncle being beneath, are called by Mr. Darwin the *terga*; the pair below it, on the same side, the *scuta*. The upper mesial valve opposed to the two terga is the *carina*, and below this the *subcarina*; and on the opposite side again the *rostrum*. Below this is sometimes a *subrostrum*. Of all the valves the scuta are the most permanent; then come the terga, and then the carina. The others occur only occasionally. The shell is generally white, occasionally reddish or purple; exteriorly the valves are covered by more or less persistent, generally yellow, strong membrane. The scuta and terga are always considerably larger than the other valves. The adductor muscle is always attached to a point not far from the middle of each scutum, which generally has a pit for its attachment. The valves are either placed close together or at some distance. The membrane connecting the valves, where they do not touch, is like that forming the peduncle, and is sometimes coloured brilliantly crimson-red; generally it is bluish-gray. Within the capitulum is the sac, which, together with the upper internal part of the peduncle, incloses the animal's body.

The Peduncle varies in length in different species, and even in the same species, according to the situation occupied by the individual. It is usually flattened, but sometimes quite cylindrical. It is composed of very strong generally thick transparent membrane, rarely coloured reddish, and often penetrated by numerous tubuli. The peduncle is lined within by thin layers of muscles, longitudinal, transverse, and oblique, all destitute of the transverse striæ characteristic of voluntary muscles. They run from the bottom of the peduncle to the base of the capitulum, as in *Lepas*, or half way up it, as in *Conchoderma*. The gentle swaying to and fro movements and the power of longitudinal contraction are produced by these muscles. The interior of the peduncle is filled up with a great mass of branching ovarian tubes.

There are six pairs of cirri. The five posterior pairs are seated close to each other and equidistant; the first pair is generally seated at a little distance and sometimes at a considerable distance from the second pair. The first pair is shortest; the others, proceeding backwards, increase gradually in length. The number of segments in the posterior cirri is very great. The cirri are covered with spines. Most of the genera have caudal appendages.

The alimentary canal consists of an œsophagus, a stomach, and rectum. The œsophagus is of considerable length; it is formed of strong transparent much-folded membrane, continuous with the outer integuments, and moulted with them. At its lower end it expands into a bell with the edges reflexed. This bell lies within the stomach, and keeps the upper broad end expanded. The stomach lies in a much-curved almost doubled course, and is often a little constricted where most bent. It is broadest at the upper end. The stomach is coated by small opaque pulpy slightly arborescent glands, believed to be hepatic. The rectum varies in length, extending inwards from the anus to between the bases of the second and fifth pair of cirri. It is narrow, and formed of much-folded transparent membrane. Within the stomach there can generally be seen, according to the period of digestion, a thin yet strong perfectly transparent epithelial membrane, not exhibiting under the microscope any structure. It enters the branching cæca, and extends from the edge of the bell of the œsophagus to the commencement of the closed rectum. It was this membrane which was supposed by M. Martin-Saint-Ange to be a distinct organ, like the closed tube of certain *Annelidæ*.

The circulatory system is not highly developed. No heart has been discovered. The whole body is permeated by channels which have no proper coat.

In most genera of the *Lepadidæ* the nervous system consists of six main ganglia, namely, the supra-œsophageal and five thoracic ganglia. Of these the first thoracic or infra-œsophageal ganglion is considerably the largest and most massive. It is squarish, or oval, or heart-shaped; it presents no trace of being formed of two lateral ganglia. Two great nerves spring from its under side, and run straight down amongst the viscera. These nerves are about as large as those forming the collar and those running to the second ganglion; hence six great nerves meet here, two in front, two behind, and two on the under side. Nerves are given off from the remaining ganglia to the cirri and other organs. The muscles of the capitulum are supplied from the supra-œsophageal ganglion.

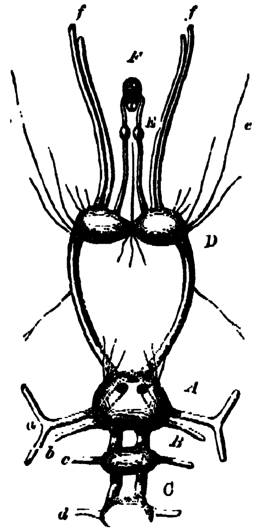

Diagram of the anterior portion of the nervous system in *Lepas fascicularis*. *A*, first thoracic or infra-œsophageal ganglion; *B*, second thoracic ganglion; *C*, third thoracic ganglion; *D*, supra-œsophageal ganglion; *E*, the two ophthalmic ganglia; *F*, double eye; *a*, nerve going to first cirrhus; *b*, to the muscles below the first cirrhus; *c*, to the second cirrhus; *d*, to the third; *e*, nerves running to the ovaria; *f*, double nerves supplying the sac and peduncle.

Nerves proceed from the supra-œsophageal to the double eye of *Lepas fascicularis*. The idea that the whole peduncle and capitulum consists of the first three segments of the head is beautifully supported by the structure of the nervous system, in which these parts are seen to be supplied with nerves exclusively from the supra-œsophageal ganglion. In ordinary *Crustaceæ* the supra-œsophageal ganglion sends nerves to the eyes and the two pairs of antennæ corresponding to the first three segments of the body.

The reproductive system of the Cirripedes has excited much interest from the results of the researches of Mr. Darwin. All the Cirripedes, with few exceptions, are bi-sexual, but Mr. Darwin has found that the masculine power of certain hermaphrodite species of *Ibla* and *Scalpellum* is rendered more efficient by certain parasitic males, which, from their not pairing, as in all hitherto known cases, with females, but with hermaphrodites, Mr. Darwin designates Complemental Males. The ordinary male organs consist of pear- or finger-shaped bodies of a leaden colour, which coat the stomach, enter the pedicles, and even the basal segments of the rami of the cirri, and in some genera occupy certain swellings on the thorax and prosoma.

With regard to the ovaria, M. Martin-Saint-Ange has described how the peduncle is gorged with an inextricable mass of branching ovarian tubes filled with granular matter and immature ova. The ova when excluded remain in the sac of the animal until the larvæ are hatched. They are very numerous, and generally form two concave nearly circular leaves, called by Darwin Ovigerous Lamellæ. The ova lie in a layer, from two to four deep, and all are held together by a most delicate transparent membrane, which separately enfolds each ovum. This membrane is often thicker and stronger round the margins of the lamellæ, where they are united in a peculiar manner, presently to be described, to a fold of skin on each side of the sac; these two folds Darwin calls the Ovigerous Fræna. As the lamellæ are formed without organic union with the parent they would be liable to be washed out of the widely-opened sac of the *Lepadidæ* if they had not been specially attached to the fræna.

The complemental males, to which we have before alluded, occur in the genera *Ibla*, *Scalpellum*, *Alcippe*, and *Cryptophialus*; and these males are permanently attached to the females. In *Ibla* the male is attached within the sac of the female; it has a well-organised mouth supported on a peduncle, but with only a rudiment of the thorax, and with only two pairs of aborted cirri. In *Scalpellum* the males differ in the different species remarkably in structure: in some of the species they are not very unlike ordinary Pedunculated Cirripedes, and are attached between the scuta of the females; in other species the males are very rudimental, extremely minute, and would never without close examination have been thought to have even belonged to the class *Cirripedia*. These males consist of a sac, with rudiments of four valves, inclosing a singularly modified thorax, with only four pairs of appendages (which cannot be called cirri); they are entirely destitute of a mouth or stomach. The males of *Cryptophialus* and *Alcippe* are even more rudimentary than those of the above species of *Scalpellum*: they are reduced to an outer envelope (homologous with the carapace of ordinary *Crustacea*), to a single eye, the testis, vesicula seminalis, and a wonderfully elongated probosciformed male organ. Hence there is no mouth, no stomach, no thorax, no abdomen, and no appendages or cirri. It may be doubted whether in the whole animal kingdom there exists a creature in a more rudimentary condition than these males. As they do not possess a mouth or stomach they are necessarily short-lived. The pupa fixes itself on the female, becomes cemented to her, undergoes its metamorphosis, and becomes a male Cirripede; the spermatozoa become developed and are discharged; the male dies, decays, and generally drops off, and is succeeded, when the ova in the female are next ready to be impregnated, by one or more fresh males. Owing apparently to the small size of the males, there is generally more than one attached to the female at the same time; and in the case of *Alcippe lampas* Mr. Darwin found no less than thirteen of these singular parasitic and rudimentary males attached to a single female!

Remarkable as is the occurrence of the above male parasites on the females, it is a far more singular fact, that in some of the species of *Ibla* and *Scalpellum*, the males are attached, not on females, but on hermaphrodites; and hence they have been called by Mr. Darwin Complemental Males, inasmuch as they are complementary to the male organs of the hermaphrodite. Mr. Darwin, in his work on the *Cirripedia* (p. 281), published by the Ray Society, enters at length on the evidence in support of this view, and he believes the facts cannot be controverted. (p. 214.) "Although the existence of hermaphrodites and males within the limits of the same species is a new fact amongst animals, it is far from rare in the vegetable kingdom: in such cases the male flowers are sometimes in a rudimentary condition compared to the hermaphrodite flowers, exactly in the same manner as are the males of *Ibla* and *Scalpellum*. If the final cause of the existence of these Complemental Males be asked, no certain answer can be given; the vesiculæ seminales in the hermaphrodite of *Ibla quadrivalvis*, and in some species of *Scalpellum*, appeared to be of small diameter; but on the other hand the ova to be impregnated are fewer than in most Cirripedes. No explanation can be given of the much simpler case of the mere separation of the sexes in the four genera before enumerated; nor can any explanation be given of the much more varied arrangement of the parts of fructification in plants of the Linnean class *Polygamia*."

The following woodcuts will give an idea of the structures above described, more especially in accordance with the views of Martin-Saint-Ange:—

Fig. 1. Anatife jaune sans coquille (Cuvier, *Alepas?*): A, a gelatinous production, the cement, which serves to fix the peduncle; B, the first membrane of the peduncle; B′ a small Cirripede, of the natural size developed upon the peduncle of the parent; C, the capitulum, which contains the body of the animal; D, the fissure of the capitulum from which issue the feet or cirri F. The point E indicates the termination of the peduncle, and the place where the eggs stop; G, the eggs arrived within the sac. *Fig.* 2. The same letters refer to the same parts as in *fig.* 1; H, the pedicles of the cirri, which sustain the rami, F. At the base of the feet (H) are four branchiæ; and between these feet and those placed on the other side is seen the recurved tube which serves to convey the seminal liquor to the ova within the sac. *Fig.* 3. The same Cirripede, from which the half of the first envelope has been taken so as to expose the interior. The peduncle contains a second cylinder terminated in a cul-de-sac by its inferior extremity, and covered at the other by a very delicate membrane; the longitudinal and transverse muscular fibres may be observed; *e*, *e*, indicate the canal which, according to Saint-Ange, carries the eggs of the peduncle within the sac; *b*, that which serves as a nourishing vessel to the peduncle and the eggs; *g*, *g*, the membrane of the sac which intercepts all direct communication between the peduncle and the cavity of the sac. J represents the body of the Cirripede inclosed in its proper envelope. *Fig.* 4. The same situation as the last, representing all the membranes which envelop the

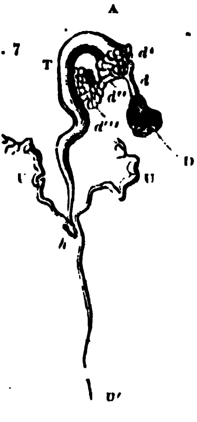

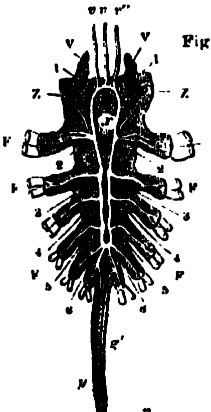

Fig. 8.

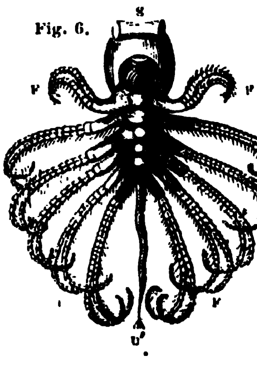
Fig. 6.



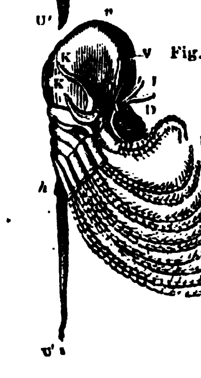


Fig. 5.

body of the Cirripede; B, B, the muscular cylindrical pipe open, in which the eggs are seen; *c*, *c*, the course of the ovarian tubes in the thickness of the second envelope; *g*, *g*, *g*, the envelope opened and turned back; J, J, J, the proper membrane of the body of the animal; it is with this cavity that the canal *b* communicates, and it is between this proper membrane and that of the second envelope *g*, *g*, *g*, that the eggs are found: whence it results that the cavity of the mantle has no communication with the peduncle, except by means of the oviduct *e*.

Fig. 5. Side view of the common Duck Barnacle (*Lepas anatifera*) taken out of the shell, enveloped in its proper membrane, under which is found the salivary (?) vesicle; V, the cervical ganglion; *v*, the nerve which is given off from the brain to go to the muscles of the skin; J, the two levator muscles of the upper lip; K K, branchiæ; *h*, a horny tubercle which is formed on each side of the orifice of the vent; U′, the extremity of the tube, bearded with fine hairs. *Fig.* 6. Anterior view of the same, showing the truly articulated disposition of the body, each ring of which corresponds to a pair of feet; S, the adductor muscle of the valves; U′, the articulated tube which contains the spermatic canal. *Fig.* 7. The intestinal canal of the same species; D, the mouth seen from the side; *d*, the œsophagus; *d′*, the stomach; *d″*, the peduncle which makes this organ communicate with a species of cæcum, *d‴*, of the same structure and form as the stomach; T, the intestinal canal, offering two natural curvatures; *h*, orifice of the rectum; U U, vesiculæ seminales, uniting in a single canal very delicate, and terminated at U′ by a small orifice. *Fig.* 8. Disposition of the nervous system: 1. The first œsophageal ganglion, called the brain: from these united ganglions spring the branches *v*, *v′*, *v″*, destined for all the muscles of the dorsal part, and two extremely delicate threads which go on each side, the first to the salivary vesicle V, the second to a new ganglion Z; 2. The second ganglion, sending two nervous branches to each jaw-foot F, and small branches to the œsophagus; 3, 4, 5, 6 correspond to the other ganglions; 6 furnishes the two last pairs of feet. It is from the branches which go to the last feet, and not from the ganglions themselves, that the two threads *y* and *y′*, which go to the extremity, U′, of the tube are detached. The point *x* corresponds to the centre of the œsophagus which has been removed.

The process of exuviation takes place in the *Cirripedia*. Mr. Darwin says, "In the *Lepadidæ*, with the exception of the genus *Lithotrya*, in which the calcareous scales on the peduncle together with the membrane connecting them is cast off, neither the valves nor the membrane uniting them, nor that forming the peduncle with its scales, are moulted; but the surface gradually disintegrates, and is removed, perhaps sometimes in flakes; whilst new, and larger layers are formed beneath. In most Sessile Cirripedes the outside membrane connecting the operculum and shell is regularly moulted. The delicate tunic lining the sac and the integuments of the whole body are periodically shed. With these integuments, the membrane lining the œsophagus, the rectum, the deep olfactory pouches, and the horny apodemes of the maxillæ are all moulted together. The new spines on the cirri are formed within the old ones.

"All *Cirripedia* grow rapidly; the yawl of H.M.S. Beagle was lowered into the water at the Galapagos Archipelago on the 15th of September, and after an interval of exactly thirty-three days was hauled in again. I found on her bottom a specimen of *Conchoderma virgata* with the capitulum and peduncle, each half an inch in length and the former $\frac{1}{20}$ths in width; this is half the size of the largest specimen I have seen of this species. Several other individuals, not half the size of the above, contained numerous ova in their lamellæ, ready to burst forth. Supposing that the larvæ of the largest specimen became attached the first day the boat was put into the water, we have the metamorphosis, an increase of length from about ·05 of a inch, the size of the larva, to a whole inch, and the laying of probably several sets of eggs, all effected in thirty-three days. From this rapid growth repeated exuviations must be requisite. Mr. W. Thompson, of Belfast, kept twenty specimens of *Balanus balanoides*, a form of much slower growth, alive, and on the twelfth day he found the twenty-first integument, showing that all had moulted once, and one individual twice within this period. I may here add that the Pedunculated Cirripedes never attain so large a bulk as the Sessile. *Lepas anatifera* is sometimes 16 inches in length, but of this the far greater portion consists of the peduncle. *Pollicipes mitella* is the most massive kind; I have seen a specimen with a capitulum two-thirds of an inch in width."

The Pedunculated Cirripedes extend over the whole world; and most of the individual species have large ranges, more especially, as might have been expected, those attached to floating objects. Excepting these latter, the greater number inhabit the warmer, temperate, and tropical seas. Of those attached to fixed objects, or to littoral animals, it is rare to find more than three or four species in the same locality. On the shores of Europe Mr. Darwin says he knows of only three, namely, *Scalpellum*, *Pollicipes*, and *Alepas*. At Madeira (owing to the admirable researches of the Rev. R. T. Lowe) two *Pœcilasmas*, a *Dichelaspis*, and an *Oxynaspis* are known. In New Zealand there are two *Pollicipes* and an *Alepas*, and perhaps a fourth form. From the Philippine Archipelago, in the great collection made by Mr. Cuming, there are a *Pœcilasma*, an *Ibla*, a *Scalpellum*, *Pollicipes*, and *Lithotrya*. Of all the *Lepadidæ* nearly half are attached to floating objects or to animals which are able to change their position; the other half are generally attached to fixed organic or inorganic bodies, and more frequently to the former than to the latter. Most of the species of *Scalpellum* are inhabitants of deep water; on the other hand most of *Pollicipes*, of *Ibla*, and of *Lithotrya* are littoral forms. The species of *Lithotrya* have the power of excavating burrows in calcareous rocks, shells, and corals; and the singular manner in which this is effected is described in Mr. Darwin's work. *Anelasma* has its sub-globular peduncle deeply imbedded in the flesh of northern sharks, and instances have occurred of the basal end of the peduncle of *Conchoderma aurita* being sunk into the skin of *Cetacea*; in the same way the point of the peduncle in the male of *Ibla* is generally deeply embedded in the sac of the female. In all these cases the cementing substance affects and injures the corium or true skin of the animal on which the creature is parasitic, while the surrounding parts being not injured continue to grow upwards, thus causing the partial embedment of the Cirripede. In the case of *Anelasma*, we have growth at the end of the peduncle, and consequently downward pressure, and this may possibly cause absorption to take place in the skin of the shark at the spot pressed on.

Arrangement of the Family. *

Class, *Crustacea;* Sub-Class, *Cirripedia.*

Crustacea attached by the anterior end of the head by cement, proceeding from a modified portion of the ovaria: archetype composed of 17 segments, with the first three of large size, and almost always developed into a carapace not wholly exuviated, and capable of various movements; antennæ none; eyes rudimentary; mouth prominent, formed by the partial confluence of the labrum, palpi, mandibles, and two pairs of maxillæ. Thorax attached to the internal sternal surface of the carapace, generally bearing six pairs of captorial, biramous, multi-articulated limbs. Abdomen generally rudimentary. Branchiæ, when present, attached to the under sides of the carapace. Bisexual; when unisexual, males parasitic on the female; male organ single, generally probosciformed, seated at the posterior end of the abdomen. Oviducts none. Metamorphosis complex.

Order I. *Thoracica.*†

Cirripedia having a carapace consisting either of a capitulum on a peduncle, or of an operculated shell with a basis. Body formed of six thoracic segments, generally furnished with six pairs of cirri. Abdomen rudimentary, but often bearing caudal appendages. Mouth with the labrum not capable of independent movements. Larva firstly uniocular, with three pairs of legs; lastly, binocular, with six pairs of thoracic legs.

Family 1.—*Balanidæ.*

Cirripedia without a peduncle; scuta and terga furnished with depressor muscles; other valves united immovably together.

This family was well known to the ancients. The genera seem to have been all confounded under the name of Βάλανος (Balanus) by the Greeks. (Aristotle, 'Hist. Anim.,' book iv. ch. 8, and book v. ch. 15.) Athenæus mentions them more than once; and ('Deipnos,' book iii. ch. 11, p. 88) speaks of the large ones with approbation as an article of food. They are the *Balani* of the Latins; nor did Lucullus disdain them. The Chinese eat the soft parts of one of the species (*Balanus tintinnabulum*), which has the reputation of being like the flesh of the lobster when cooked; and the delicious qualities of another species, and its high estimation for the table, are referred to in another place. [BALANUS.]

Sub-Family.—*Balaninæ.*

Shell with the rostrum without alæ, but having radii; the lateral compartments all with alæ on one side and radii on the other; parietes generally either porose or longitudinally ribbed on their inner surfaces.

Section ‡.

Scutum and tergum articulated together or overlapping each other: each branchia composed of a single plicated fold.

Genus, *Balanus* Auctorum.—Compartments six; basis calcareous or membranous; opercular valves sub-triangular. [BALANUS.]

---

* We are indebted to Mr. Darwin for the following arrangement, the first volume of whose great work on the *Cirripedia*, including the *Lepadidæ*, published by the Ray Society has alone at present been published.

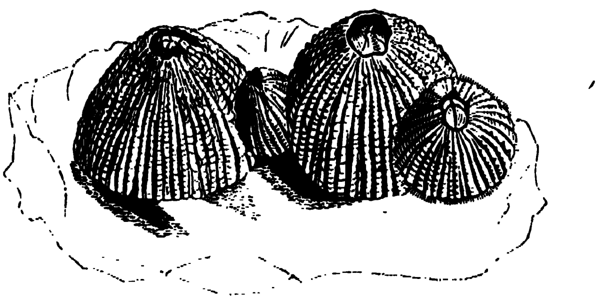
† The external parts of Cirripedes consist either of a *Shell* with an *Operculum* and the *Basis*, or of a *Capitulum* (as called by Mr. Darwin), which is homologous with the shell and operculum, mounted on a *Peduncle*, which again is homologous with the basis. The two valves, to which the animal's body is attached, and which have the power of opening and shutting, are called by Mr. Darwin the *Scuta;* a second pair of valves, bounding the orifice, at that end at which the cirri are exserted, are called the *Terga*. At this same end of the shell, or capitulum, the medial valve or compartment is called the *Carina;* the medial valve or compartment at the opposite end is called the *Rostrum:* the principal valves or compartments on each side are called the *rostro-lateral*, *lateral*, and *carino-lateral*, or simply the lateral compartments or *Latera*. In the *Balanidæ* each separate compartment may be said to consist of the *wall* or *parietal* portion (generally wedge-formed, with the apex upwards), and with a *Radius* (either on one or both sides), or with an *Ala* (either on one or both sides): the *Ala* is a quadrangular projection, always overlapped by the adjoining compartment; the *Radius* has usually the shape of a wedge, with the apex downwards; it is exterior, and overlaps the adjoining compartment.

This, the typical genus of the family, includes 39 recent species, which range from 77° in the northern hemisphere to Cape Horn in the south.

Sub-genus, *Acasta,* Leach, 1817.—Compartments six; parietes and basis non-porose; basis calcareous, cup-formed, not elongated: attached to sponges or rarely to the bark of Isis.

This sub-genus, which is a very natural one in habits and appearance, nevertheless can hardly be distinguished from those species of *Balanus* which live attached to *Gorgoniæ.* *Acasta* is found in almost all parts of the world.

Tetraclita, Schumacher, 1817 (*Conia* of Leach, *Asemus* of Ranzani).—Compartments four, sometimes with their outer laminæ calcified together; parietes permeated by pores, generally forming several rows; basis flat, irregular, calcareous or membranous.

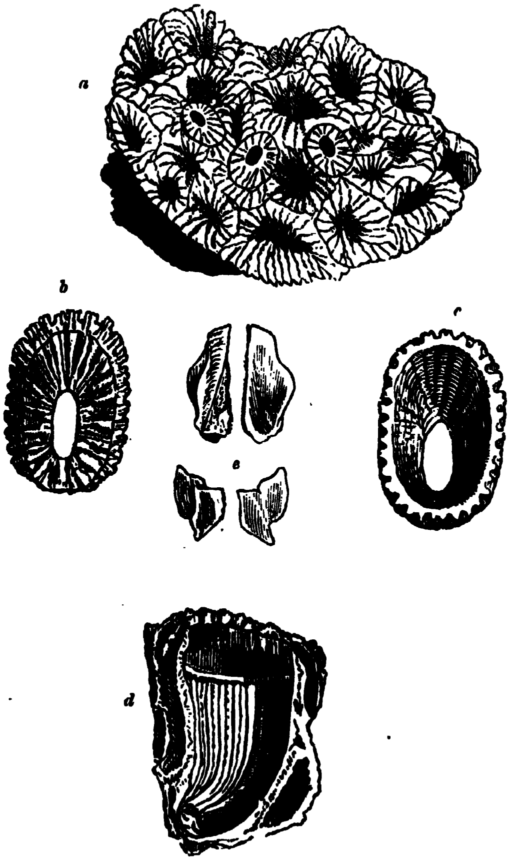


Tetraclita porosa.

Elminius, Leach, 1825.—Compartments four; parietes not porose; basis membranous.

This genus is confined to the southern hemisphere.

Pyrgoma, Leach, 1817 (*Megatrema* of Leach; *Adna* of Leach; *Daracia* of J. E. Gray; *Creusia* of De Blainville; *Nobia* of Sowerby).—Shell formed of a single piece; basis cup-formed or sub-cylindrical: attached to, or imbedded in corals.



Pyrgoma crenatum.

a, specimens of the natural size in *Astræa favosa; b, c, d,* different views and section of the cone; *e,* the opercular valves. *b, c, d,* and *e,* are magnified.

Sub-genus *Creusia,* Leach, 1817.—Compartments four; furnished with radii; basis cup-formed, imbedded in corals.

This sub-genus is most closely allied to *Pyrgoma,* and its separation is of doubtful propriety.

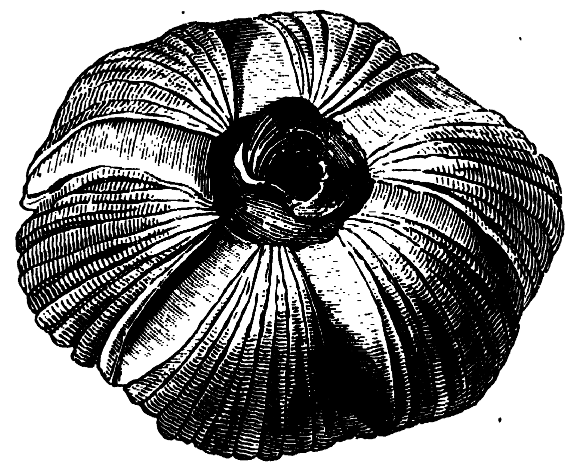
Chelonobia, Leach, 1817 (*Coronula* of Lamarck; *Astrolepas* of Gray).—Compartments extremely thick, six in number, but the rostrum is internally composed of three compartments united together; basis membranous; scuta narrow, united to the terga by a horny articular ridge.

Two of the three species included in this genus are always attached to turtles; the third adheres to crabs and smooth shells.

Section ††.

Scutum and tergum (when both are present) not overlapping each other; basis membranous; parietes often deeply folded, with the outer lamina towards the basis generally imperfect; each branchia composed of two plicated folds: shell attached to living *Vertebrata.*

Coronula, Lamarck, 1802 (*Diadema* of Schumacher; *Cetopirus* of Ranzani).—Compartments six, of equal breadth, deeply folded, with the folds outwardly pressed together, but inwardly expanded, so as to form cavities open only on the under side; opercular valves much smaller than the orifice of the shell: attached to *Cetacea.*

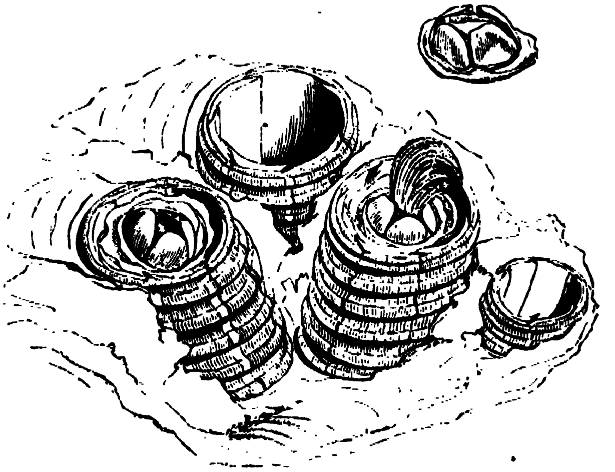


Coronula balænaris.

Platylepas, J. E. Gray, 1825 (*Coronula* of De Blainville).—Compartments six, each bilobed and inwardly produced, so as to form six mid-ribs, which support the outwardly convex membranous basis.

The species of this genus are attached to turtles, manatees, and sea-snakes.

Tubicinella, Lamarck, 1802 (*Coronula* of De Blainville).—Compartments six, of equal breadth; shell sub-cylindrical, wider at the top than at the basis; belted by several transverse ridges: attached to *Cetacea.*



Tubicinella trachealis.

Xenobalanus, Steenstrup, 1852.—Shell almost rudimentary, star-formed, composed of six compartments, with a long peduncle-formed body rising from the middle of them; opercular valves none: attached to *Cetacea.*

Sub-Family.—*Chthamalinæ.*

Shell with the rostrum having alæ, but without radii; rostro-lateral compartments without alæ on either side; parietes not porose.

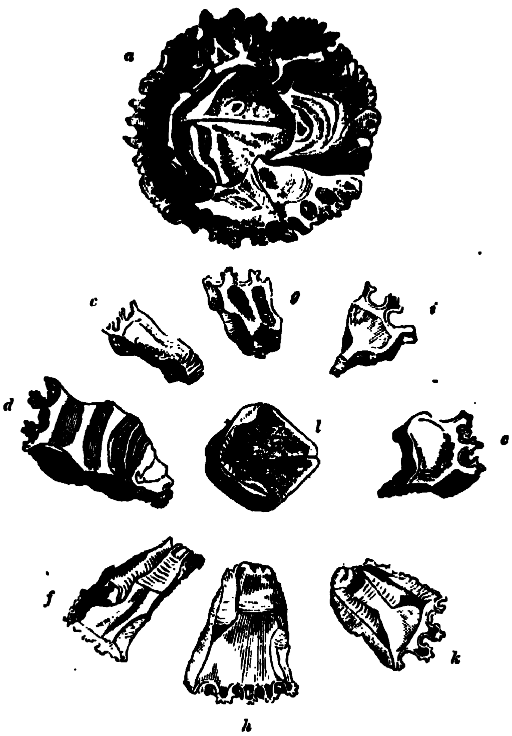
Chthamalus, Ranzani, 1820 (*Euraphia,* Conrad).—Compartments six; basis membranous, but sometimes in appearance calcareous from the inflected parietes.

Chthamalus stellatus.

Chamæsipho, Darwin, 1854.—Compartments four, with the sutures often much obliterated; basis membranous.

Pachylasma, Darwin, 1854.—Compartments, when the shell is very young, eight; when maturer, either six, or in appearance only four, from the close union of the lateral compartments; basis calcareous.

Octomeris, G. B. Sowerby, 1825.—Compartments eight; radii with their edges crenated; basis membranous.

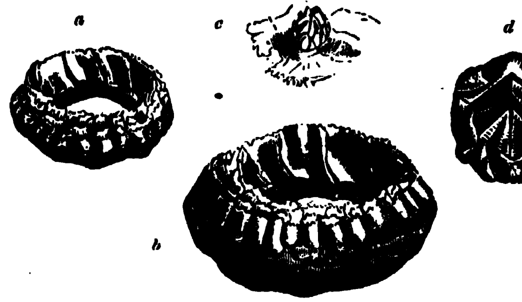


Octomeris angulosa.

a, the outside; below, an internal view of the eight divisions; *c*, the anterior piece; *d*, the posterior piece; *e* to *k*, the lateral pieces; *l*, the operculum, consisting of four pieces, of which the two anterior are the larger.

Catophragmus, G. B. Sowerby.—Compartments eight, with several exterior whorls of small supplemental compartments; basis either membranous or calcareous.

"The shell," says Mr. G. B. Sowerby, "consists in a number of narrow perpendicular valves arranged around the shelly cone, and in rows, like pales, the first row of which consists of eight pieces, placed so as exactly to cover the sutures of the shelly cone immediately surrounding the animal; around this are then placed several sets of more and more numerous pieces gradually decreasing in size, so that the outer row, which is the most numerous, consists also of the smallest pieces. Additional rows seem to be produced as the animal increases in age; for a young specimen in our possession has only one row of eight pieces covering the sutures of the first cone, while a much larger and older specimen still retains part of three rows, and has evidently lost some of the external rows. The young individual also shows that the whole of the pieces are pointed at their superior extremities, whereas in the old shell these extremities are so worn or eroded as to become very irregular and obtuse."



Catophragmus imbricatus.

a, the old shell, natural size; *b*, the same magnified; *c*, the young shell, natural size; *d*, the same magnified.

Family II.—*Verrucidæ.*

Cirripedia without a peduncle; scuta and terga not furnished with depressor muscles, moveable only on one side, on the other side united immoveably with the rostrum and carina into an asymmetrical shell.

Verruca, Schumacher, 1817 (*Clisia* and *Clitia* of Leach, *Creusia* of Lamarck, *Ochthosia* of Ranzani).—This genus is very remarkable in many respects, especially in its asymmetrical shell; sometimes the right side and sometimes the left side being specially modified. It includes four recent species.

Verruca Strömia.

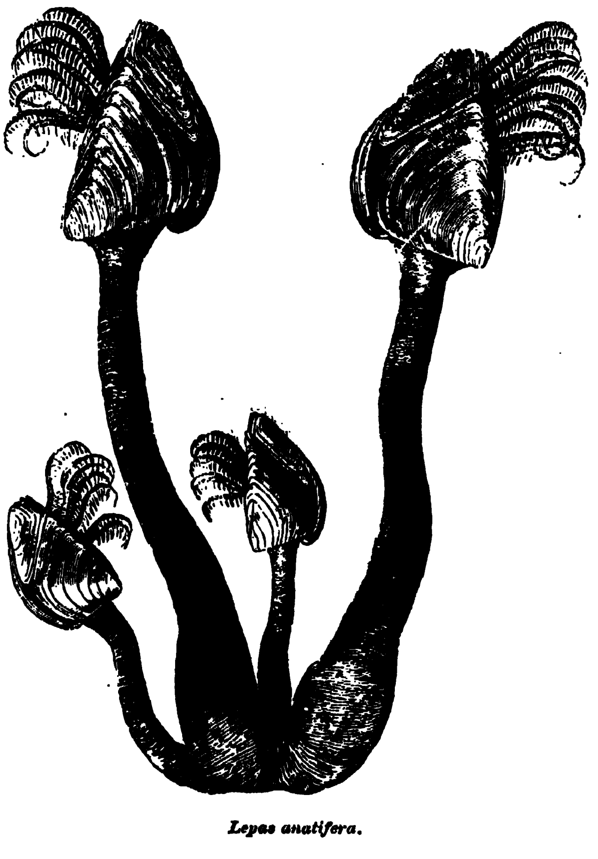
Family III.—*Lepadidæ.*

Cirripedia having a flexible peduncle, provided with muscles; scuta and terga (when present) not furnished with depressor muscles; other valves (when present) not united into an immoveable ring.

The genera of this family affix themselves by means of their peduncle to submarine bodies, forming numerous groups. They are often found on floating substances far at sea: on ships, on logs of timber, on bottles, on net-corks, on fuci, on floating testaceous mollusks, *Ianthina* for instance, and even on some of the vertebrated animals, on whales, turtles, and even serpents—*Hydrophis*, for example. Other testaceous mollusks might be mentioned, and one species has been found parasitical within the umbrella of a *Medusa.* A large log of timber covered with these animals, twisting and diverging in all directions, and so thick as entirely to hide the surface of the log, is a strange sight. They look like an enormous collection of serpents to the ignorant; and we have heard a living mass of this description casually thrown into shallow water and left by the tide so termed. Their growth must be extremely rapid. A ship going out with a perfectly clean bottom will often return from a short voyage covered with them below the water-line. The Blacks of Goree are said to eat a large species of *Pentalasmis,* which is stated to be delicate.

Lepas.—Valves 5, approximate; carina extending up between the terga, terminating downwards in an imbedded fork or in an external disc; scuta subtriangular with their umbones at the rostral angle. The species are found all over the world attached to floating objects.

L. anatifera, the Common Barnacle. It is the *Anatifa*, *Anatifera*, and *Pentalasmis* of many authors. *Anatifa engonata* of Conrad; *A. dentata* (var.) of Bruguières; *Pentalasmis dentatus* of Brown; *Anatifa* of Martin-Saint-Ange. The valves are smooth or delicately striated. Right hand scutum alone furnished with an internal umbonal tooth; uppermost part of peduncle dark-coloured. It is extremely common, attached to floating timber, vessels, sea-weed, bottles, &c., and to each other.



Lepas anatifera.

Mr. Darwin describes also the following species :—*L. Hillii, L. anserifera, L. pectinata, L. australis, L. fascicularis.*

Pœcilasma, Darwin.—Valves 3, 5, or 7, approximate; carina extending only to the basal points of the terga, with its lower end either truncated or produced into a deeply imbedded disc. Scuta nearly oval, with their umbones at the rostral angle. This genus embraces the following species :—*P. Kæmpferi, P. aurantia, P. crassa, P. fissa, P. eburnea.* Four out of the five species live attached to *Crustacea* in the European and Eastern warmer, temperate, and tropical oceans. The fifth species was found attached to the dead species of an *Echinus* off New Guinea. It is probable that several more species may be discovered.

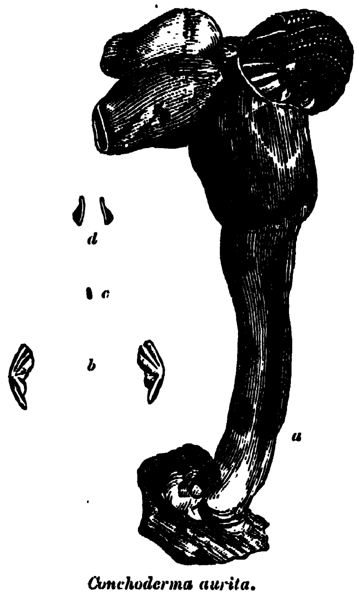
Dichelaspis, Darwin (*Octolasmis*, J. E. Gray; *Heptalasmis*, Agassiz).—Valves 5, generally appearing like 7, from each scutum being divided into two distinct segments, united at the rostral angle; carina generally extending up between the terga, terminating downwards in an imbedded disc or fork, or cup. The following are the species ;—*D. Warwickii, D. Grayii, D. pellucida, D. Lowei, D. orthogonia.* The species are very rare. They have been found attached to crabs at Madeira and off Borneo, and attached to sea-snakes in the Indian Ocean.

Oxynaspis, Darwin.—Valves 5, approximate; scuta with their umbones in the middle of the occludent margin; carina rectangularly bent, extending up between the terga, with the basal end simply concave. The only species is *O. celata*, which was found attached in numbers to an *Antipathes* in Madeira, by the Rev. R. T. Lowe.

Conchoderma, Olfers (*Lepas*, Linnæus; *Branta*, Oken; *Malacotta* and *Senoclita*, Schumacher; *Otion* and *Cineras*, Leach; *Gymnolepas*, De Blainville; *Pamina*, J. E. Gray).—Valves 2 to 5, minute, remote from each other; scuta with two or three lobes, with their umbones in the middle of the occludent margin; carina arched, upper and lower ends nearly alike.

C. aurita, Darwin. It is the *Lepas aurita*, Linnæus; *Otion Cuvieranus, O. Blainvillianus, O. Bellianus, O. Dumerillianus, O. Rissoanus*, Leach; *O. depressa, O. sacculifera*, Coates; *O. auritus*, Macgillivray; *Lepas Seporina*, Poli; *Lepas cornuta*, Montagu; *Conchoderma auritum, C. leporinum*, Olfers; *Branta aurita*, Oken; *Malacotta bivalvis*, Schumacher; *Gymnolepas Cuvieri*, De Blainville.

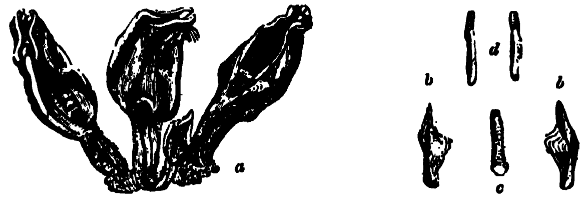
The capitulum has two ear-like appendages seated behind the rudimentary and often absent terga; scuta bilobed; carina absent or quite rudimentary; peduncle long, distinctly separated from the capitulum. This species is extremely common in every ocean. It is found on ships' bottoms from all parts of the world. It is found in the Arctic and Antarctic Oceans, not unfrequently on the coronulæ on whales, and on slow-moving fish. It is often associated with other species. The earlike appendages are the most extraordinary part of this animal. Mr. Darwin thinks that their function is respiratory.



Conchoderma aurita.

a, entire animal; *b*, the lateral valves; *c*, the single valve; *d*, the terminal valves.

C. virgata, Darwin. It is the *C. virgatum*, Olfers; *Lepas virgata*, Spengler; *L. coriacea*, Poli; *L. membranacea*, Montagu; *Branta virgata*, Oken; *Senoclita fasciata*, Schumacher; *Cineras vittata*, Leach; *C. membranacea*, Macgillivray; *C. bicolor, C. vittatus*, Brown; *Gymnolepas Cranchii*, De Blainville; *Pamina trilineata*, J. E. Gray. The scuta 3-lobed; terga concave internally, with their apices slightly curved inwards; carina moderately developed, slightly curved; peduncle blending into the capitulum.



Conchoderma virgata.

a, Animal. *b*, the scuta; *c*, the carina; *d*, the terga.

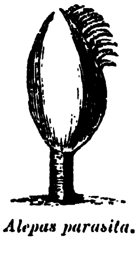
Like the last, this species is extremely common on ships' bottoms from all parts of the world. It also attaches itself to sea-weed, turtles, and other objects.

The small valves in *C. aurita* were overlooked by Lamarck, but detected by Leach. In the Museum of the Royal College of Surgeons, 'Nat. Hist.,' No. 265, there is a species named *Cineras Hunteri*, of which two small groups are attached to the tail of *Hydrophis bicolor*, which is figured in Russell's 'Indian Serpents,' 1, tab. xli., and is called by the natives 'Nalla Wahlagillee Pam.' Russell says, "This sea-snake, according to the Vizagapatam fishermen, seldom approaches the shore; several of them had never seen one before. They pretended it was of a very dangerous kind, which is contradicted by the want of poisonous organs."

C. Hunteri is admitted as a species by Mr. Darwin. It has however scarcely more claim to be regarded as a species than some of the varieties of the first two species.

Alepas, Sander Rang (*Anatifa*, Quoy and Gaimard; *Triton*, Lesson; *Cineras*, Lesson).—Capitulum without valves, or with horny almost hidden scuta.

M. Rang has given the generic appellation above stated to the *Cineras parasita* of Lesson, and the *Anatifa univalvis* of Quoy and Gaimard. The species on which the genus was founded was detected attached to the umbrella of a *Medusa.* Rang considers this to be the *Triton* of Linnæus. Cuvier, in the last edition of the 'Règne Animal,' observes that he has not seen the species, but still adheres to his old opinion; for he says that it ought not in any case to be confounded with the *Triton* of Linnæus, which was the animal of an *Anatifa* torn from its mantle and shell.



Alepas parasita.

A. parasita, Sander Rang. It is the *Anatifa univalvis* and *A. parasita*, Quoy and Gaimard; *Triton* (*Alepas*) *fasciculatus*, Lesson. Orifice not protuberant, equalling two-thirds of the length of the capitulum; scuta horny. Total length two inches.

It has been found parasitic on *Medusæ* in the Mediterranean and Atlantic oceans and on the south shore of England.

Three other species—*A. minuta, A. cornuta*, and *A. tubulosa*—are described by Darwin.

Anelasma, Darwin; *Alepas*, Loven. Capitulum without valves, aperture large, peduncle fimbriated, sub-globular, imbedded.

A. squalicola, Darwin, is the only species of this genus. It was referred by Loven to *Alepas*, but has been separated by Darwin. It lives parasitic, with its peduncle imbedded in the skin of sharks in the North Sea.

Alcippe, A. Hancock, 1849. Capitulum without valves, with the aperture spinose; peduncle grows at its lower end, rostral surface depressed and covered by a horny disc; capitulum and peduncle imbedded in a self-formed cavity.

This most remarkable genus bores cavities for itself in shells. It inhabits the shores of England. It has but one species, *A. lampas*, Hancock.

Ibla, Leach (*Anatifa*, Cuvier; *Tetralasmis*, Cuvier).—Female and hermaphrodite with 4 horny valves; peduncle clothed with persistent horny spines.

There are two species of this, *I. Cumingii* and *I. quadrivalvis.* This is one of the genera in which complemental males occur, the structure of which Mr. Darwin has described at great length. *I. Cumingii* inhabits the seas of the Philippine Archipelago, and they are invariably attached to the peduncle of *Pollicipes mitella* in groups of two or three together. *I. quadrivalvis* is found in the Australian seas.

Scalpellum, Leach (*Lepas*, Linn.; *Pollicipes*, Lamarck; *Polylepas*, De Blainville; *Smilium*, Leach; *Calantica*, J. E. Gray; *Thaliella*, J. E. Gray; *Anatifa*, Quoy and Gaimard; *Xiphidium*, Dixon).—Hermaphrodite and female with valves 12 to 15 in number; latera of the lower whorl 4 or 6, with their lines of growth generally directed towards each other; sub-rostrum very rarely present; peduncle squamiferous, most rarely naked.

S. vulgare, Leach. It is the *Lepas Scalpellum*, Linnæus; *Pollicipes Scalpellum*, Lamarck; *Polylepas vulgare*, De Blainville; *Scalpellum læve*, Leach. Hermaphrodite with capitulum of 14 valves, including

Scalpellum vulgare.

the rudimentary rostrum; upper latera irregularly oval. The complemental male flask-formed, with four rudimentary valves.

It is a native of the seas of Great Britain, Ireland, France, Norway, and Naples. Found attached to horny corallines, according to Forbes and MacAndrew, at from twenty to thirty, sometimes even to fifty fathoms in depth. There are five other species of this genus. They are all characterised by the presence of the complemental male.

Pollicipes, Leach (*Lepas*, Linnæus; *Anatifa*, Bruguières; *Mitella*, Oken; *Ramphidionia*, Schumacher; *Polylepas*, De Blainville; *Capitulum*, J. E. Gray).—Valves from 18 to above 100 in number; latera of the lower whorl numerous, with their lines of growth directed downwards; subrostrum always present; peduncle squamiferous.

P. mitella, Sowerby. It is *Lepas mitella*, Linnæus; *Polylepas mitella*, De Blain.; *Capitulum mitella*, Gray. Capitulum with only one whorl of valves under the rostrum; the upper pair of latera viewed internally are three or four times as large as the lower latera, which overlap each other laterally; scales of the peduncle symmetrically arranged in close whorls.

Pollicipes mitella.

This species is found in the seas of the Philippine Archipelago and the Chinese Sea. There are five other species. They are found attached to both fixed and floating objects in the warmer, temperate, and tropical seas.

Lithotrya, G. B. Sowerby (*Litholepas*, De Blainville; *Absia*, Leach; *Brismæus* and *Conchotrya*, J. E. Gray; *Lepas*, Gmelin; *Anatifa*, Quoy and Gaimard).—Valves 8, including a small often rudimentary rostrum and a pair of small latera; lines of growth finely crenated; peduncle covered with small calcareous scales; those of the upper whorls crenated; attached either to a basal calcareous cup or to a row of discs.

Mr. G. B. Sowerby, who instituted the genus, considers it as intermediate between the Sessile and Pedunculated Cirripedes; and states that it possesses a peculiarity not to be found in any hitherto described genus of this class, namely, that of penetrating stones for its habitation. Rang says that De Blainville is of opinion that the genus is only a true *Anatifa*, which had affixed itself upon the valve of a *Venerupis* at the bottom of one of the cavities which that bivalve hollows out for itself. De Blainville, in his 'Malacologie,' describes it under the name of *Litholepas*, sinking Sowerby's name altogether, though he says the genus was newly established by him, quotes his description, and merely states that he has never seen the Cirripede.

As the means by which many of the *Mollusca* bore into the rocks in which they reside are at present unknown and are matters of much discussion, the conclusions at which Mr. Darwin has arrived with regard to the species of *Lithotrya* are of high interest. After describing accurately the structure of the valves, the peduncle, the muscles of the peduncle, the basal calcareous cups or discs, and the internal structure of the cup, he concludes:—"The several species occur imbedded in soft calcareous rocks, in massive corals, and in the shells of *Mollusca* and of Cirripedes. It has been doubted by several naturalists whether the basal calcareous cup at all belongs to the *Lithotrya*; but after the foregoing microscopical observations on its structure it is useless to discuss this point. So again it has been doubted whether the cavity is formed by the cirripede itself; but there is so obvious a relation between the diameters of specimens of various sizes and the holes occupied by them that I can entertain no doubt on this head. The holes moreover are not quite cylindrical, but broadly oval, like the section of the animal. The simple fact that in this genus alone each fresh shelly layer round the bases of the valves, and therefore at the widest part of the capitulum, is sharply toothed; and secondly, that in this genus alone a succession of sharply-serrated scales, on the upper and widest part of the peduncle, is periodically formed at each exuviation, and that consequently the teeth on the valves and scales are sharp and fit for wearing soft stone at that very period when the animal has to increase in size, would alone render the view probable that the *Lithotrya* makes or at least enlarges the cavities in which it is imbedded. Although it may be admitted that *Lithotrya* has the power of enlarging its cavity, how does it first bore down into the rock? It is quite certain that the basal cup is absolutely fixed, and that neither in form nor state of surface it is at all fit for boring. I was quite unable to answer the foregoing question until seeing the admirable figures by Reinhardt of *L. Nicobarica* still attached in its cavity. Subsequently I obtained from Mr. Stutchbury several pieces of rock completely drilled with holes, many of small diameter, by *L. dorsalis*; and in these I found numerous instances of the linear rows of little discs like those of *L. Nicobarica*, showing in the plainest manner that each time a new disc is formed, that is, at each exuviation, the animal moves a short step downwards; and as the lowest of these little discs in none of the burrows was placed at the very bottom, we see that the lowest point of the peduncle must be the wearing agent. In the peduncle of an individual of *L. dorsalis*, nearly ready to moult, I found, it may be remembered, beneath and round the basal disc, under the old membrane of the peduncle, a new membrane studded with calcified beads, but with the horny star-headed spines not yet developed; whilst on the old outer coat these latter had been worn down quite smooth, and the calcified beads worn entirely away. Here then we have an excellent rasping surface. With respect to the power of movement necessary for the boring action, the peduncle is amply furnished with transverse, oblique, and longitudinal striæless muscles, the latter attached to the basal disc. In all the *Pedunculata* I have reason to believe that these muscles are in constant slight involuntary action. This being the case, I conceive that the small blunt spur-like portion of the peduncle descending beneath the basal rim of the lowest disc would inevitably partake slightly of the movements of the whole distended animal. As soon as the *Lithotrya* has reached that depth which its instincts point out as most suitable to its habits, the discs are converted into an irregularly growing cup, and the animal then only increases in diameter, enlarging its cavity by the action of the serrated scales on the peduncle, and of the serrated lower edges of the valves of the capitulum. With respect to those reversed individuals attached with their capitulums downwards, I suppose that the larvæ had crept into some deep cavity perhaps made originally by a *Lithotrya*, of which the rock in the specimen in question was quite full, and had there attached themselves. Finally, it appears that in *Lithotrya* the burrowing is simply a mechanical action: it is effected by each layer of shell in the basal attached discs overlapping in a straight line the last-formed layer; by the membrane of the peduncle and the valves of the capitulum having excellent and often renewed rasping surfaces; and lastly, by the end of the peduncle (that is, homologically the front of the head) thus roughened, extended beyond the surface of attachment, and possessing the power of slight movement."

L. dorsalis, G. B. Sowerby. It is the *Lepas dorsalis*, Ellis; *Litholepas* de Mont Serrat, De Blainville. Scuta narrowly overlapping the terga; carina internally concave; rostrum as wide as two or three of the subjacent scales; latera with their internal surfaces narrowly elliptical, as long as five of the subjacent scales; upper scales of the peduncle less than twice as large as those in the second whorl.

Lithotrya dorsalis.

This species is found imbedded in limestone at Barbadoes, Venezuela, and the Honduras.

L. cauta, Darwin, named from a unique specimen, was found imbedded in a *Conia* or *Tetraclita* from New South Wales.

L. Nicobarica, Reinhardt, is a rare species occurring in the Nicobar Islands.

L. Rhodiopus, Darwin, is named from a specimen imbedded in a massive coral in the British Museum.

L. truncata, Darwin, found imbedded in coral rock in the Friendly Islands and Philippine Archipelago.

L. Valentina, Darwin, from two specimens imbedded in an oyster-shell, in the British Museum, from the Red Sea.

Order II. *Abdominalia*

Cirripedia having a flask-shaped carapace. Body consisting of 1 cephalic, 7 thoracic, and 3 abdominal segments, the latter bearing 3 pairs of cirri; the thoracic segments without members; mouth with the labrum greatly produced, and capable of independent movements; œsophagus armed with teeth at its lower end; larva firstly egg-like, without external limbs or an eye; lastly, binocular, without thoracic legs.

This order contains only one genus and one species, *Cryptophialus minutus*, Darwin, 1854. It is very distinct from all other Cirripedes, but more nearly allied to *Alcippe* amongst the *Lepadidæ* than to any other form. It bores cavities in the *Concholepas Peruviana*, and is of very minute size.

Order III. *Apoda.*

Cirripedia with the carapace reduced to 2 threads, serving for attachment. Body consisting of 1 cephalic, 7 thoracic, and 3 abdominal segments, all destitute of cirri; mouth suctorial, with the mandibles and maxillæ, placed back to back, inclosed in a hood, formed by the union of the labrum and palpi; metamorphoses unknown.

This order, like the last, contains only one genus and species, *Proteolepas bivincta*, Darwin, 1854. It was found parasitic within the sac of another Cirripede in the West Indies. Until most closely examined the *Proteolepas* would never have been imagined to have belonged to the class of *Cirripedia*. In external appearance it resembles the larva or maggot of a fly; its mouth is unlike that of any known type in the articulate kingdom.

Fossil Cirripedia.

As with the recent so with the fossil species of this family, we are most indebted for our knowledge of them to the exhaustive labours of Mr. Darwin, whose recent investigations on this subject have thrown all others into the shade. The result of his inquiries into the extinct history of the *Cirripedia* has been given in a work published by the Palæontographical Society, which, although more immediately intended to illustrate the fossil Pedunculated Cirripedes of Great Britain, embraces an outline of the whole subject as far as it is known. In our remarks we shall follow Mr. Darwin. "No true Sessile Cirripede," he says, "has hitherto been found in any Secondary formation. Considering that at the present time many species are attached to oceanic floating objects, that many others live in deep water in congregated masses, that their shells are not subject to decay, and that they are not likely to be overlooked when fossilised, this seems to be one of the cases in which negative evidence is of considerable value." Often observers have searched with great care amongst the Secondary rocks and have met with nothing that bear the characters of the *Balanidæ* of the present day. The Sessile Cirripedes are first met with in the Eocene deposits of the Tertiary formations, and subsequently often in abundance in the same formation. They appear however never to have abounded so greatly as at the present time, so that Mr. Darwin says, "The present period will hereafter apparently have as good a claim to be called the age of Cirripedes as the Palæozoic period has to be called the age of Trilobites." He adds, "There is one apparent exception to the rule that Sessile Cirripedes are not found in Secondary formations, for I am enabled to announce that Mr. J. de C. Sowerby has in his collection a *Verruca* from our English Chalk; but this genus, though hitherto included amongst the Sessile Cirripedes, must, when its whole organisation is taken into consideration be ranked in a distinct family of equal value with the *Balanidæ* and *Lepadidæ*, but perhaps more nearly related to the latter than to the Sessile Cirripedes."

The oldest known Pedunculated Cirripede is a species of *Pollicipes* discovered by Professor Buckman in the Stonesfield Slate in the Lower Oolite, and two species of the same genus have been described by Mr. Morris from the Oxford Clay in the Middle Oolite. No Cirripede has yet been found in the Upper Oolite, or in the Wealden Beds. During the development of the great Cretaceous system, the *Lepadidæ* arrived at their culminating point. At this time there existed 3 genera and at least 32 species, some occurring at every stage of the system. In addition to the species described there are several doubtful, and by future research many more will undoubtedly be added to the present list.

Although rich in species, the individuals in the Chalk oceans seemed to have been rare, if we may judge from the few remains of particular species that exist in any one collection. It is not always the case that a great variety of species is attended with a multiplicity of individuals, although that is frequently observed.

In the Eocene, Miocene, and Pliocene Tertiary deposits, Mr. Darwin has met with but two species of *Scalpellum* and two of *Pollicipes*, distinct from recent forms. Two or three species are doubtful. It is a singular fact that, widely distributed as are the species of *Lepas* at the present day, and the frequency of the individuals, not a single valve known certainly to belong to this genus or to any of the closely allied genera, has hitherto been found fossil.

The following is a table of the species described in Mr. Darwin's monograph:—

Table of Distribution of Species and the Formations where they are found.

Scalpellum magnum . .	Tertiary.
S. quadratum . . .	Tertiary.
S. fossula	Upper Chalk.
S. maximum	Faxoe. Scania. Maestricht. Upper Chalk.
S. lineatum . . .	Lower Chalk.
S. hastatum	Chalk Marl.
S. augustum . . .	Upper Chalk (?), Lower Chalk (?), Chalk Marl (?).
S. quadricarinatum . .	Chalk Marl.
S. trilineatum . . .	Chalk Marl.
S. simplex	Lower Greensand.
S. arcuatum . . .	Gault.
S. tuberculatum . . .	Upper Chalk, Lower Chalk, Chalk Marl.
S. solidulum . . .	Scania. Upper Chalk.
S. semiporcatum . . .	Scania. Upper Chalk.
S. Cretæ (?)	Upper Chalk.
Pollicipes concinnus . .	Lower Greensand.
P. Ooliticus . . .	Lower Oolite.
P. Nilssonii	Scania. Upper Chalk.
P. Hausmanni . . .	Gault.
P. politus	Upper Greensand (?).
P. elongatus . . .	Upper Chalk.
P. acuminatus . . .	Lower Chalk.
P. Angelini . . .	Scania. England. Upper Chalk.
P. reflexus	Tertiary.
P. carinatus . . .	Tertiary.
P. glaber	Upper Chalk, Lower Chalk, Chalk Marl.
P. unguis	Gault, Lower Greensand.
P. validus	Scania. Maestricht. Upper Chalk.
P. gracilis	Upper Chalk, Lower Chalk.
P. dorsatus	Faxoe. Upper Chalk.
P. striatus	Upper Chalk.
P. semilatus	Upper Chalk, Lower Chalk, Chalk Marl.
P. rigidus	Gault.
P. fallax	Scania. England. Hanover. Upper Chalk.
P. elegans	Faxoe. Scania. Upper Chalk.
P. Bronnii	Upper Greensand.
P. planulatus . . .	Lower Greensand.
Loricula pulchella . . .	Lower Chalk.

CIS, a genus of Coleopterous Insects of the family *Ptinidæ* (Leach). They are minute Beetles which infest the various species of *Boleti.* They are of an oblong nearly cylindrical form, and generally of a brown colour: their tarsi are 4-jointed, and the antennæ have the basal joint large, and the three apical joints forming a club. Fourteen species have been discovered in this country, the largest of which is scarcely one-eighth of an inch in length.

CISSA'MPELOS, a genus of Plants belonging to the natural order *Menispermaceæ*. It is diœcious; the sepals 8, in a triple series; the stamens united into a slender column dilated at the apex, bearing two 2-celled anthers opening horizontally. The species are twining shrubs with triangular leaves, shining on the upper and pubescent on the under surface.

C. Pareira, the Pareira-Brava, is a native of several of the West India Islands, of Mexico, and of Brazil. The root of this plant arrives in Europe in pieces from two to three feet long, varying in thickness from that of a finger to an arm, curved, furrowed, and warty, with a thin closely-adhering bark of a grayish-brown colour. The woody part is tough, but so porous that air can be blown from one end to the other of a long piece; the concentric circles are very conspicuous; the axis is not in the centre. The odour is very faint, but the taste is at first sweetish or liquorice-like, afterwards nauseous and bitter. Analysed by Feneuille it was found to consist of—soft resin; a yellow bitter principle (tonic); a brown principle; animalised matter, starch, malate of lime, nitrate of potash, and other salts. The juice of the fresh plant in its native country is said to be a very efficacious application to the bites of serpents; but in Europe the root is employed only as a tonic diuretic.

There is great reason to believe that the roots of several different species of this or closely-allied genera are confounded under the name of Pareira-Brava, especially the root of *C. Caapeba*, also of *C. Mauritanica* (Aubl.), which is much esteemed in the East Indies given along with aromatics in diseases of the intestines. Several other species of *Cissampelos*, on account of their prominent bitter properties, have been used in medicine. Two species of *Abuta*, an allied genus, *A. rufescens* (Aubl.), and *A. candicans* (Decand.), are used in Guyana under the name of White and Red Pareira-Brava.

CISSUS. [VITACEÆ.]

CISTA'CEÆ, a natural order of Polypetalous Exogenous Plants, belonging to Lindley's Calycose Group; among which they are known by their opposite or alternate undivided leaves, generally strongly impregnated with a fragrant resinous secretion, regular flowers with crumpled petals and indefinite stamens, and fruit with parietal placentæ; a simple style, and a large number of seeds containing in the midst of albumen an embryo with the radicle remote from the hilum. They are remarkable for the beauty of their fugitive flowers in the genera *Cistus* and *Helianthemum.* [CISTUS; HELIANTHEMUM; COCHLOSPERMUM.] The relations of *Cistaceæ* are with *Cruciferæ*, *Capparidaceæ*, *Sterculiaceæ*, and *Hypericaceæ*. It contains 7 genera and about 190 species. They are chiefly found in the south of Europe and the north of Africa. They are rare in North America, extremely uncommon in South America, and scarcely known in Asia. (Lindley, 'Vegetable Kingdom.')

CISTELA. [CISTELIDES.]

CISTE'LIDES, a family of Coleopterous Insects of the section *Heteromera* and sub-section *Stenelytra.* The species have the following characters:—Claws of the tarsi pectinated beneath; antennæ with the basal joint free, that is, not covered by a projecting portion of the head; mandibles with the apex entire.

This family includes the genera *Lystronichus*, *Cistela*, *Mycetocharus*, *Allecula*, and some others.

Lystronichus.—Of this genus there are upwards of thirty species known; their colouring is for the most part brilliant and metallic; by far the greater portion of them are found in South America. They have the thorax depressed, and with the posterior part as wide as the elytra, or nearly so; the antennæ are filiform, sometimes growing slightly thicker towards the apex.

Cistela.—The characters of this genus are:—Head long and somewhat pointed in front; labrum in width and length nearly equal; antennæ rather long, sometimes serrated, or with most of the joints triangular; body elongate-ovate; thorax broader behind than before.

Nearly forty species of this genus are known, most of which inhabit Europe, and four or five are found in this country.

C. Ceramboides is nearly half an inch in length; black with ochre-coloured elytra, and, like most of the insects of this section, is found in flowers.

C. sulphurea (*Allecula sulphurea* of some authors) is about one-third of an inch in length, and its colour is pale-yellow throughout. This species is more common in this country than the last, and appears to be confined chiefly to the sea-coast, where, like the one above mentioned, it is found in flowers.

Mycetocharus.—In this genus the head is short and rounded, and the labrum is transverse; the antennæ are shorter and the body is more elongate than in *Cistela.* About ten species are known, most of which inhabit Europe and North America; but one is found in England (*Mycetocharus scapularis*); this is about three-sixteenths of an inch in length; black; the elytra with two orange-coloured spots at the base; the base of the antennæ and the tibiæ and tarsi are yellow.

The larvæ of this insect, together with those of one or two other species of the *Cistelides,* are figured in the first volume of the 'Entomological Society's Transactions,' where an account of their habits will also be found.

The genus *Allecula* (Latreille) may be distinguished from either of the foregoing genera by the species having the penultimate joint of the tarsi bilobed, and the terminal joint of the palpi securiform.

Upwards of thirty species of *Allecula* have been discovered, most of which inhabit South America.

CISTUDO. [CHELONIA.]

CISTUS, a genus of Plants belonging to the natural order *Cistaceæ.* The calyx is composed of 5 nearly equal sepals in a double row; corolla of 5 equal petals, somewhat cuneated, caducous; the stamens numerous; style filiform; stigma capitate; the capsule superior, 5- or 10-celled, loculicidal; the seed ovate, singular; the embryo filiform, spiral. The species are shrubs or undershrubs with opposite leaves and one- or many-flowered peduncles. The flowers are either red or white, large, resembling a rose.

C. Creticus, Cretan Rock-Rose, has spathulate ovate and oblong leaves, somewhat hairy, downy, dull green, somewhat wavy at the edge, and stalked; the petioles furrowed, nearly distinct, the peduncles 1-flowered; sepals with a long taper point and villous; white flowers. It is a native of dry hills in the most southern parts of Europe. It has evergreen leaves which emit a balsamic odour when rubbed, or after damp warm weather in the summer. It yields, with many other species of *Cistus,* a gum-resin called Ladanum [LADANUM, in ARTS AND SC. DIV.], formerly in great repute as a stimulant in medicine, and still used by the Turks as a perfume.

Cretan Rock-Rose (*Cistus Creticus*).

C. laurifolius, the Laurel-Leaved Gum-Cistus or Rock-Rose has stalked ovate-lanceolate 3-nerved leaves, with the upper surface glabrous and the under surface tomentose; the footstalks dilated and connate at the base; the capsule 5-celled. It is a native of the south of France and Spain. It has white flowers with a yellow mark at the base of each petal.

C. ladaniferus, Gum-Cistus, has almost sessile leaves, connate at the base, linear lanceolate, 3-nerved, the upper surface glabrous, the under surface tomentose; the capsule 10-celled. It is a native of the hills of Spain and Portugal. Two varieties are described, one with white petals having a yellow spot at the base, the other with white petals and a blood-coloured spot at the base.

C. Ledon has connate leaves, oblong lanceolate, nerved; upper surface smooth, shining, under surface silky villous; the flowers in corymbose cymes; the peduncles and calyx clothed with silky villi. It is a native of the south of France. All the species of *Cistus* here enumerated are said to yield the Gum Ladanum. Many species which were formerly described under *Cistus* are now referred to *Helianthemum.* [HELIANTHEMUM.] This is the case with the whole of the old British species of *Cistus.* The flowers of both these genera are very beautiful, and are remarkable for lasting only one day, opening with the rising of the sun in the morning and perishing with the setting sun of the evening. All the species of *Cistus* are worthy of cultivation in gardens. They should be kept in the greenhouse in the winter, although during mild seasons and against a south wall they will survive in the open air. They may be propagated by seeds as layers, or by ripened cuttings procured in July or August, which, if planted under a hand-glass, will root readily.

(Don, *Dichlamydeous Plants;* Lindley, *Flora Medica.*)

CITHARI'NUS, a genus of Fishes belonging to the family *Salmonidæ.* The species inhabit the Nile. These fishes are chiefly distinguished from their allies by the depressed muzzle, the upper margin of the mouth being formed of the intermaxillary bones, the maxillaries being very small. The tongue and palate are smooth; the adipose fin is covered with small scales as well as the greater portion of the caudal fin.

CITRON. [CITRUS.]

CITRUS, a genus of Aurantiaceous Plants, one of whose species yields the Orange, another the Lemon, and others the Citron, Shaddock, Lime, and similar fruits. Among the other genera of the natural order to which it belongs, it is known by its stamens being numerous and irregularly combined into several parcels, and by its fruit having a leathery rind which can be easily separated from the pulpy part that lies beneath.

It is a common opinion that the golden apples of the Hesperides were the fruit of some species of this genus; but as the gardens of these fabulous personages were stationed, according to the most approved opinions, either among the mountains of Atlas or to the west of them, there is no probability that the opinion alluded to is correct; for, independently of the historical facts that citrons and lemons at least were obtained from the Persians, it is certain from the researches of Wallich and other Indian botanists that it is among the lower ranges of hills in Nepaul, and most probably in China also, that the wild states of the genus *Citrus* find a home. It is added that the Sweet Orange itself comes from the southern provinces of China and the Malayan Archipelago, but it is by no means clear that the plant in those countries is really wild. It is however beyond all question also of eastern origin.

Eight species are enumerated by Risso, whom we follow in the present article: we regard it, however, as a matter of great doubt how far they are really distinct. The Orange, the Lemon, the Lime, and the Citron were all that could be distinguished amongst the mass of specimens collected for the East India Company in Nepaul; and there is no great difficulty in believing that all the numerous varieties now cultivated in every part of the temperate and tropical zones, both of the Old and New World, have in reality sprung from these four original sources; part of them being natural varieties obtained by long cultivation, and part being hybrids created by accidental circumstances or artificial means.

1. *Citrus Aurantium,* the Sweet Orange (Oranger of the French, Arancio of the Italians). Stem arborescent. Leaves ovate-oblong, acute, a little serrulated, with the stalk more or less winged. Flowers white. Fruit many-celled, roundish, very seldom pointed, golden-yellow or tawny. Cysts in the rind convex. Pulp very sweet. The principal varieties of this species are :—

a. The China Orange, with ovate-oblong leaves; round smooth rather flattened fruit; and a thin golden-yellow rind. This is the Common Orange of the markets, and of the Portuguese.

b. The Pear-Shaped Orange, with elliptical acute leaves, and great top-shaped fruit, with a deep yellow smooth rind; a rare and curious sort not known in the market; it is one of the most capable of resisting cold.

c. The Orange of Nice, with ovate-acute leaves, and large, thick-skinned, rough, dark-yellow, round fruit. This is considered one of the finest of the whole genus, both in regard to beauty, size, productiveness, and quality. It is a good deal cultivated about the town whose name it bears.

d. The Tiny-Fruited Orange, with ovate-oblong acute leaves, tiny globose fruit, and a thin smooth golden-yellow rind. Supposed to have been brought from the Philippines. The fruit is more curious than beautiful or good.

e. The Fingered Orange, with little stiff leaves, and ovate fruit, some one at least of whose lobes is separate from the remainder, and horned; rind pretty thick. This must not be confounded with the Fingered Citron hereafter to be mentioned.

f. The Blood-Red Orange, with ovate-oblong pellucid leaves, and middle-sized round rough reddish-yellow fruit, with a pulp irregularly mottled with crimson. This, which is said to have come from the Philippines, was once looked upon as a great curiosity, and living plants were purchased at a considerable price; it was thought to be produced by grafting an orange upon a pomegranate. Now that it is known to be a variety of indifferent quality, and that its fabulous history is forgotten, it has ceased to attract much notice. A trifling variety of it is the Arancio di Sugo Rosso of the Italians, who call the real blood-red variety Arancio di Malti Sanguigno. Another variety, with small fruit, is the Arancio a Foglia Stretta of Nice.

g. The Ribbed Orange, with oblong-acute leaves, and a flattened ribbed deep-orange fruit. This is one of the most tender of the varieties; its fruit is spongy, and of no value.

h. The Sweet-Skinned Orange, with broad taper pointed leaves, roundish rather ovate heavy fruit, and a deep yellow smooth thick sweet soft rind. This is the Pomme d'Adam, or Forbidden Fruit, of the shops of Paris. Its pulp is subacid and pleasant, and as deep a yellow as the rind, which is soft and melting like the flesh of a cling-stone peach; the acidity of the pulp is agreeably mixed with sweetness, and renders the fruit extremely pleasant. This is very different from the Forbidden Fruit of the London shops; see *C. decumana* further on.

i. The Mandarin Orange, with flattened rough deep-orange fruit, and a thin rind, which separates spontaneously from the pulp. This sort has been raised in China, where its fruit is chiefly consumed in presents to the great officers of state, whence its name. It is now cultivated in Malta, where it arrives at perfection. Its singularity consists in the rind so completely separating from the pulp when quite ripe that the latter may be shaken about in the inside. In quality this yields to no known kind. There are two sub-varieties.

k. The Saint Michael's Orange, with small round pale-yellow seedless fruit, having a thin rind and an extremely sweet pulp. This, when in a state of perfection, is perhaps the most delicious of all the oranges, and it is by far the most productive. Great quantities are imported from the Azores, where it appears to be exclusively cultivated as an object of trade. It is said that 20,000 of these oranges have been packed from a single tree, exclusively of the large quantity which were blown down or rejected as unfit for sale.

Besides these there are numerous other sorts to be found in the gardens of the curious, and in commerce are many kinds about which little is known. Among these may be mentioned the Egg-Oranges of Malta, which are sometimes sent to England as presents; they are not however equal in quality to the China or the Saint Michael's varieties.

2. *C. Bigaradia*, the Bigarade, or Bitter Orange (Bigaradier of the French, Melangolo of the Italians). Branches spiny. Leaves elliptical, acute, with a winged stalk. Flowers very white. Fruit middle-sized, uneven, more or less globose, deep yellow, with an acid and bitter pulp. It differs moreover from the sweet orange in forming a smaller tree, having broader leaves, and larger and sweeter flowers, on which account it is always selected in preference for the purposes of the perfumer. Its fruit is much more uneven. Numerous varieties of it are known, among which are all those cultivated for the sake of their flowers; especially the Horned Bigarade, a variegated variety of it, and the Curled-Leaved Bigarade. The following are a few of the most striking forms of this species:—

a. The Horned Bigarade, with a large pale-yellow ribbed fruit, whose sides project into horns. This variety, which is of the same nature as the Fingered Sweet Orange (var. *c.*), its horned appearance being caused by the separation of the carpels or fruit-lobes, is in great estimation on account of the powerful and delicious perfume of its flowers. It is the Melangolo a Frutto Cornuto of the Italians.

b. The Female Bigarade, with a deep yellow large coarse fruit, containing orange within orange. The circumstance from which this variety derives its name is not at all uncommon in the genus *Citrus*, but it exists here in perhaps the most strongly-marked manner. An orange in its natural state consists of one whorl of carpels, which are consolidated into a round fruit, each of whose lobes is one carpel. But it sometimes happens that two whorls of carpels combine to form the same fruit; in that case the inner whorl is consolidated into a central orange, and the outer whorl grows over it. Or it may happen that three whorls of carpels constitute the fruit; in that case the innermost whorl will combine into an orange in the centre; the second whorl will form a coating over it; and the most exterior whorl will inclose the whole. Finally the carpels may separate wholly, as in the Fingered Citron, or in part, as in the Fingered Orange and Bigarade, and then the fruit consists of a number of lobes more or less distinct. Until the discovery made by Göthe of the real nature of compound fruit, oranges of this kind were looked upon as something wondrous, and many idle speculations existed as to their cause. A figure of this may be found in Risso's 'Histoire Naturelle des Orangers,' t. 33, without however any explanation of the cause of the monstrosity.

c. The Curled-Leaved Bigarade, with very compact blunt small curled leaves, and flowers growing in thick clusters at the ends of the branches. No variety is more generally cultivated than this for the sake of its flowers, which are large, sweet, and produced in extraordinary profusion. The French gardeners call it Le Bouquetier, or Nosegay Plant, and Bigaradier Riche Dépouillé; the Italians Melangolo Ricco. The fruit is coarse, very light, uneven, and with a large conspicuous scar at the point. The plant itself is far more dwarf than the other varieties, and is one of the most robust of its race. It is a common object of cultivation all over the South of Europe.

d. The Purple Bigarade, with leaves, flowers, and fruit stained more or less with a dull purple, especially the young leaves. Hermaphrodite and Bigarade Violette of the French, Melangolo Pavonezzo of the Italians.

e. The Double-Flowered Bigarade, with rather thick leaves, double flowers, round granulated fruit, and a thick rind; the common double orange of the nurseries. It is a great favourite in gardens, because of its multitudes of fragrant double flowers, which do not fall in pieces so quickly as those which are single; it loses its quality of producing double flowers if the soil in which it grows is not kept in a very rich state.

f. The Seville Bigarade or Orange, with round dark fruit, having an uneven rugged extremely bitter rind; commonly brought to the English market, where it is consumed in the manufacture of bitter tinctures, and in the preparation of candied orange-peel. The bitter aromatic principle is a powerful tonic; it gives its flavour to the liqueur called Curaçoa.

g. The Myrtle-Leaved Bigarade, with small very compact ovate sharp-pointed leaves, and small round fruit; generally both in flower and fruit at the same time, if well cultivated. On this account and because of its dwarf habit, it is a very common object in gardens. It is said to be a Chinese production, and that it is employed by the Chinese gardeners as an edging of flower-beds, in the same way as the dwarf box in this country.

h. The Bizarre Bigarade, with curled rather deformed leaves, purplish or white flowers, and fruit of different sorts, some being round and of the common appearance, others half bigarades and half lemons or citrons, the pulp of some being sweet, that of others acid and bitter. A curious lusus naturæ, which was once thought to be the greatest prodigy in all the vegetable kingdom. It is however merely one of those sports, as they are technically called by gardeners, in which, owing to some unknown cause, some one individual assumes the appearance of two or more others in particular parts. Analogous instances are—the grape called the Variegated Chasselas, some of whose fruit is black, some white, and some striped with both colours; the Camellia, which bears red, white, and party-coloured flowers on the same stem; and the Chrysanthemum, some of whose flowers are purple and others yellow. This Bigarade was raised from seed by a gardener at Florence in 1644, and has since been multiplied by grafting, and so has been preserved to the present day. It may be procured from the nurserymen of France and Italy, and it fruits annually in the orangery at Versailles.

3. *C. Bergamia*, the Bergamot Orange. Leaves oblong, flowers small, very sweet. Fruit pear-shaped or flattened, rugged, with a greenish-yellow smooth rind filled with concave receptacles of oil. Pulp subacid, very fragrant. The trees of this species are rather variable in appearance. The fragrance of both flowers and fruit is peculiar. From each of them the perfumer procures an essence of a delicious quality. The rind, deprived of the pulp, first dried, and then moistened with water, is pressed in moulds into fancy boxes for holding lozenges and other sweetmeats, and these boxes retain much of their recent odour. The Mellarosa of the Italians is a variety, with ribbed fruit, having a broad scar at the summit; it is much esteemed on account of the abundance of its flowers.

4. *C. Limetta*, the Lime. Leaves ovate, obovate, and oblong, placed upon a wingless stalk. Flowers small and white. Fruit ovate or roundish, pale-yellow, with a boss at the point; the cysts in the rind concave; pulp subacid. In foliage this resembles the lemon, but its fruit differs in the pulp never having the sharp and powerful acid of the lemon; it is on the contrary flat and slightly bitter: it is principally employed for flavouring punch, sherbet, and similar drinks. The varieties are of no importance; they principally differ in the thickness of their rind and in form. Here is to be arranged the round very uneven fruit called Pomo d'Adamo by the Italians, because they fancy that the depressions upon its surface look as if they still bore the marks of our universal father's teeth.

5. *C. decumana*, the Shaddock. Leaves large, with a winged stalk. Flowers very large and white. Fruit usually very large, roundish, pale yellow, smooth, with flat or convex cysts in the rind. Rind white, spongy, very thick; pulp juicy, sweetish, rather insipid. Shaddocks are among the largest fruits which are known, and are commonly cultivated in both the East and West Indies for the sake of the delicate subacid juicy pulp in which they abound. When they arrive at their greatest size they are called Pompoleons or Pompelmousses; when at the smallest they form the Forbidden Fruit of the English markets. Another small variety, with the shaddocks

rowing in clusters, forms a larger tree than any other *Citrus*; the ruit is about as large as the fist; it is what the West Indians call the rape-Fruit.

6. *C. Lumia*, the Sweet Lemon. Leaves like those of the lemon. lowers red externally. Fruit with the flesh and rind of a lemon, ut with the pulp sweet, and the cysts in the rind both convex and oncave. There can be no doubt that this is a mere variety of he next species, from which it only differs in the want of acidity in he pulp. Many sorts are known in orange countries, of which one, he Commander's Pear, resembles very much a large Beurré Pear; heir fruit is seldom seen in England.

7. *C. Limonum*, the True Lemon (Citronnier of the French). Leaves ovate-oblong, usually serrulated, pale green, with a winged stalk. Flowers middle-sized, red externally. Fruit oblong, very uneven, now and then almost round, with a pale-yellow fragrant rind, dotted with concave cysts. Pulp juicy, and very acid. Of this species the cultivators take little pains to distinguish the varieties. When young plants are wanted they are generally raised from seeds in the orange countries, and hence the samples of fruit sent to market consist at all times of numerous sorts, differing very much in quality. Some of them have their rind so thick and insipid that they approach the Citron in quality; one, with roundish rugged ribbed fruit, is called Vignette upon the Continent, where it is common; another, with oblong extremely rugged fruit, is one of the Poncires of the French. The most distinct race is that which comprehends the Perettes, or Little Pears; they are very small in the fruit, which is a pale greenish-yellow, and has almost the shape of an egg: their rind is more delicately perfumed than that of common lemons.

8. *C. medica*, the Citron (Cedratier of the French, Cedro, Cedrato, of the Italians). Branches short and stiff. Leaves oblong, toothed. Flowers purple externally. Fruit usually large, warted, and furrowed, with an extremely thick spongy rind, and a subacid pulp. This is an exceedingly variable species, chiefly valued for the fragrance of the rind of the fruit, from which a delicate sweatmeat is prepared. The Citron, supposed to be the Median, Assyrian, or Persian apple of the Greeks, is probably the most beautiful species of the genus. It is described by Risso as having a majestic aspect, shining leaves, and rosy flowers, which are succeeded by fruit whose beauty and size astonish the observer at the same time that their sweet odour gratifies his senses. The trees are constantly in vegetation, the flowers appear even in midwinter, and there is so continual a succession of them, that flowers, young fruit, and ripe fruit, may always be seen together at the same moment. The Poncire Citrons are eight or nine inches long, and are the largest of the race known in Europe.

In China there is an enormous variety, with its lobes all separating into fingers of different shapes and sizes, whence its name of Fingered Citron. The Chinese esteem it very much, both for its rarity and for the grateful odour of its rind. They place the monstrous fruits upon porcelain dishes, and have them in their apartments to fill the air with fragrance. Those who would study this genus in detail will find excellent figures of above 100 varieties in Risso's 'Histoire Naturelle des Orangers.' For the culture, medicinal uses, and commerce of the genus *Citrus*, see ORANGE, in ARTS AND SC. DIV.

CIVET. [VIVERRIDÆ.]

CLA'DIUM (κλάδος, a branch or twig), a genus of Plants belonging to the natural order *Cyperaceæ*. It has 1-2-flowered spikelets, 5 or 6 glumes, the lower ones empty and smaller, bristles absent, the nut with a thick fleshy coat, tipped with the slender base of the style. There is but one European species of this genus, the *C. Mariscus*, Common Sedge. It has lateral and terminal repeatedly compound panicles, the spikelets capitate, the stem roundish, leafy, smooth; the leaves rough on the margins and keel. It is not a common plant in Great Britain, except in Cambridgeshire, where in the bogs and fens of that county it is exceedingly common, hundreds of acres being covered entirely with it. It is used in many districts of Cambridgeshire for the purpose of lighting fires. This plant is the *Schœnus Mariscus* and *Cladium Germanicum* of many botanists. Several species of *Cladium* are natives of Australia. (Babington, *British Bot.*; Burnett, *Outlines*.)

CLA'DIUS, a genus of Hymenopterous Insects of the family *Tenthredinidæ*. It has the following characters:—Antennæ about the same length as the body, ciliated beneath, and nine-jointed; the two basal joints short, the third joint with a protuberance beneath at the base, and a branch thrown out from the upper side at the apex; the fourth and fifth have likewise the last-mentioned process; and in the sixth and seventh it is rudimentary. In the female all these processes are wanting, excepting the one on the underside of the third joint. Wings with one marginal and three sub-marginal cells; tarsi simple.

C. difformis, when the wings are expanded, measures in width about one-third of an inch: it is black, with the tibiæ and tarsi pale yellow. This species may be considered the type of the genus. It inhabits this country, but is not common.

CLADOCO'RA, a Fossil genus of Corals allied to *Lithodendron*, and occurring in the Palæozoic strata.

CLA'DODUS, a genus of Fossil Placoid Fishes, from the Mountain imestone of Armagh, Bristol, &c. (Agassiz.)

CLADO'NIA, a genus of Plants belonging to the natural order *Lichenes*. It has a thallus somewhat shrubby, branched, rarely simple, leafy, with scales, which are often evanescent; branches cartilaginous, rigid, fistulose, all attenuated and subulate, divided, fertile, generally perforated in the axils. Shields sessile, orbicular, convex, capituliform, not bordered, fixed by the circumference, free beneath in the centre, the sides reflexed, uniform within. The genus *Cladonia* thus defined, with *Scyphophorus* and *Pycnothelia*, are included by Acharius and Delisle in the genus *Cenomyce*. Sir W. Hooker observes of this genus, that "the determination of the species is attended with the greatest difficulty, on account of their variable character; and in the present state of my knowledge I dare not venture upon introducing others than those published in English Botany. Much attention has been given to this genus by Delisle in the 'Botanicum Gallicum,' who, with Acharius, unites this and the two following genera into one, *Cenomyce*, and enumerates fifty-three species, besides many marked varieties, as natives of France; all of which are most probably natives also of Britain. He would render an acceptable service to British Botany who should undertake a monograph of the British *Cladonieæ*." Hooker enumerates only five British species.

C. rangiferina, Rein-Deer Moss, has erect, elongated, roughish, cylindrical, greenish-white, very much branched podetia, the axils perforated, the branches scattered, often intricate divaricated, the alternate ones drooping, apothecia subglobose, brown, on small erect branchlets. This is a frequent plant in Great Britain, on moors, heaths, and mountains. Its botanical characters are very variable, more especially the colour and the length of the ramifications. This may be accounted for by the wide range of latitude in which it is found, extending from the arctic regions, where it is most abundant, to the tropics. This plant is the principal support of the rein-deer in its native countries, and hence its common name. In Lapland there is no plant so abundant as this, especially in the pine forests, where it covers the surface of the soil for many miles together like snow. On the destruction of the forests by fire this plant continues to grow, and then reaches its greatest luxuriance. In such districts the rein-deer are principally pastured in the winter; and whatever may be the depth of snow, these animals are enabled to obtain their food by grubbing with their noses through the snow. It would be quite impossible that the rein-deer should exist in these climates during the winter were it not for this apparently insignificant plant. The Laplanders are also in the habit of collecting this lichen with rakes in the rainy season, when it is flexible, and readily separates from the ground where it has grown; they then lay it up in heaps to serve as fodder for their cows. Dr. Clarke and his companions, during his travels in Lapland, were tempted to eat some of this lichen. "To our surprise," he says, "we found that we might eat of it with as much ease as of the heart of a fine lettuce. It tasted like wheat bran. But after swallowing it there remained in the throat and upon the palate a gentle heat or sense of burning, as if a small quantity of pepper had been mixed with the lichen. We had no doubt that if we could have procured oil and vinegar it would have made a grateful salad. Cooling and juicy as it was to the palate, it nevertheless warmed the stomach when swallowed, and cannot fail of proving a gratifying article of food to man or beast during the dry winter of the frigid zone. Yet neither Laplanders nor Swedes eat of this lichen." This might arise from the fact which Dr. Clarke relates shortly after, namely, "that when Gustavus III. succeeded to the throne an edict was published and sent all over Sweden, recommending the use of this lichen to the peasants in time of dearth, and they were advised to boil it in milk." Such an edict would be likely to have the effect of preventing people from eating it, as it would from that time forth be only looked upon as a last resource. Dillenius however states that when boiled in water it yields no jelly, its substance is very little diminished, and becomes drier than before; and the decoction evaporated yields only a small quantity of an acerb and austere extract. The alimentary secretion of this plant appears to be similar to that of other lichens. It is called Lichenin, or Lichen Starch, and contains the same elements as starch. No nitrogen has been detected. It is however probable that nitrogen will be found to exist in this lichen, as during the winter it supplies the rein-deer with food which must require a nitrogenous compound in order to maintain its muscular power, unless we have recourse to the supposition that starch or lichenin, by union with free nitrogen in the system, can be converted into fibrine or other proteinaceous compounds.

C. vermicularis, Vermicelli Lichen, has its podetia spreading horizontally, pure white, subulate, simple or slightly branched, branches tapering at each end. It has been found not unfrequent on the loftiest mountains of the north of England and Scotland. The shape of its branches give it the appearance of a bundle of small worms or of vermicelli. It is a native of South America, where it is used as a stomachic under the name of *Contrayerba blanca*.

C. sanguinea has a leafy very thick imbricated thallus, scarlet, and frosted with white beneath; above, green and somewhat gelatinous; the lobes crenulated, ascending; podetia nearly solid, cavernous, split into fingered lobes, either wholly or at their apex only; the shields marginal, confluent, scarlet. This pretty form is a native of the Brazils, where it is rubbed down with sugar and water, and is found to be an excellent remedy for aphthæ in children. The remaining described British species are *C. uncialis*, *C. pungens*, *C. furcata*.

(Lindley, *Flora Medica;* Burnett, *Outlines of Botany;* Hooker, *British Flora*, vol. ii.)

CLADYODON, a generic title for some Fossil Reptiles found in the New Red-Sandstone System. [THECODONTS.]

CLAKIS. [BERNICLE GOOSE.]

CLANGULA, a genus of Birds belonging to the family *Anatidæ*.

CLARY. [SALVIA.]

CLATHRA'RIA, a genus of Fossil Plants found in the Wealden strata of Sussex by Dr. Mantell. The stem is reticulated on the surface, and has analogies to *Xanthorrhœa* and the *Cycadeæ*. *Clathraria Lyellii* and *Cl. Mantelli* (this latter the fruit) are described by Brongniart ('Hist. des Végét. Foss.').

CLATHRO'PTERIS, a remarkable genus of Fossil Ferns, the foliation of which is marked with quadrangular network of vessels—a rare circumstance in living ferns—such as *Meniscium*. *Clathropteris meniscioides* occurs in the Mesozoic Sandstone of Hör in Scania.

CLAUSILIA, a genus of Palmoniferous *Mollusca*. [HELICIDÆ.]

CLAVAGELLA, a genus of Testaceous Acephalous Animals, established by Lamarck in the fifth volume of the 'Histoire Naturelle des Animaux sans Vertèbres,' published in 1818, and arranged by him under his Tubicolées, between *Aspergillum* and *Fistulana*. He described four species, all fossil, referring at the same time to the 'Annales du Muséum,' where he had figured the first of them under the name of *Fistulana echinata*. Lamarck thus defines the genus:—"A tubular shelly sheath, attenuated and open anteriorly, terminated posteriorly in an ovate subcompressed club beset with tubular spines; the club presenting on one side the one valve fixed in its wall or substance, while the other valve remains free in the tube."

The genus was only known in a fossil state to conchologists, when Mr. George Sowerby observed in the British Museum a recent specimen, which he at first thought might be an *Aspergillum*, inclosed in a mass of stone. On application to Mr. Children, that gentleman allowed Mr. Sowerby to examine it more closely, and on scraping away some of the investing stone the latter found *Clavagella aperta*, the first recorded recent species, and figured and described it in his 'Genera of Recent and Fossil Shells.' The same naturalist, on the return of Mr. Samuel Stutchbury from his voyage to some of the Australian and Polynesian Islands, described and figured (1827) a second species, *Clavagella australis*, three specimens of which were with difficulty obtained by Mr. Stutchbury at North Harbour, Port Jackson, in a siliceous grit like that of the coal-measures, where their presence was betrayed just beneath low-water mark, by their forcible ejection of the water from the aperture of their tubes: the specimen of *Clavagella australis* figured by Mr. Sowerby is also in the British Museum. In 1829 Mr. Henry Stutchbury, in arranging the collection of Mr. Isaac Lyon Goldsmid, suspected the presence of a *Clavagella* in a mass of *Astræopora*, and, on fracturing the specimen, laid open two individuals of another species, *Clavagella elongata*, Broderip. According to Cuvier, and a notice in the 'Annales des Sciences Naturelles' (tome xvii., p. 78), M. Audouin (1829) described a recent species, and M. Rang, in his 'Manuel des Mollusques' (1829), mentions another, apparently *Clavagella rapa*.

Still the animal remained unknown; when, on the return of Mr. Cuming from his first voyage, that zealous collector produced another specimen which fortunately included the soft parts. A fragment of calcareous grit was dredged up by Mr. Cuming from a depth of eleven fathoms, at the island of Muerte, in the Bay of Guayaquil, and in this was the greater portion of the chamber and tube, both valves, and the animal of *Clavagella lata* of Broderip. Mr. Broderip, who has described this and two other recent species in the first volume of the 'Transactions of the Zoological Society' (p. 261), says, that a close examination of the recent species has convinced him that though one valve is always fixed or imbedded in the chamber, and soldered, as it were, to the tube, so as to make one surface with it, the tube is not necessarily continued into a complete testaceous clavate shape. In Mr. Goldsmid's best and largest specimen, the fixed valve was imbedded in the coral, and though continued on to the tube or siphonic sheath, was surrounded by the wall of the coral chamber at its anterior extremity. In the other specimen the fixed valve was also continued on to the tube. In the first-mentioned specimen of *Clavagella elongata*, at the anterior or greater end of the ovate chamber, an insulated or shelly plate had been secreted with tubular perforations; that part of the chamber having afforded (apparently at a former period) the best communication with the ambient fluid: but a calcareous deposit having almost entirely cut off that communication, the animal seemed to have been compelled to secrete a second shelly plate towards the anterior ventral edge of the fixed valve, where the perforation of some other shell (a *Lithodomus* probably) secured the necessary influx of water. Nor is this the only instance of the secretion of a second tubular plate which has fallen under Mr. Broderip's notice. In the last-mentioned or smaller specimen, the perforated shelly plate joins the anterior ventral edge of the fixed valve laterally, that point of the chamber being evidently the most practicable for communicating with the water by means of the tubules: the rest of the anterior edge of the fixed valve is surrounded by the coral wall. In Mr. Cuming's specimen the fixed valve is continued on to the tube. The anterior edge of this valve is surrounded by the naked wall of the chamber, and the greater end of the chamber, or that part of it which is opposite to this anterior edge, being impracticable, from its thickness, as a water communication (with a small exception, which, not improbably, had ceased to be available), the animal had been driven to secrete the perforated shelly plates not far from the throat of the tube on either side, where the chambers of *Petricolæ* or *Lithodomi* opened a passage to the surrounding water.

Professor Owen, from an examination of Mr. Cuming's specimen, has given an account of the anatomy of this mollusk. ('Zool. Trans.,' vol. i.) He found the following to be the relative position of the animal:—The mouth turned towards the closed end of the chamber, which is consequently the anterior part. The heart and rectum near the side where the valves are connected by the ligament, or the dorsal part. The visceral mass projecting towards the opposite or neutral side. The siphon extending into the commencement of the calcareous tube, which leads out of the anal or posterior part of the chamber. The fixed valve, which covers the rough surface of the porous rock or coral, like the tiling of a chamber-floor, and affords a smooth polished surface for the support and attachment of the animal, is the left valve: the right valve remains free, or is connected only to the soft parts and cardinal ligament, in order to assist in the excavating and respiratory actions.

The shelly substance of the fixed valve passes without interruption into that of the tube; a slight ridge circumscribing the entry of the tube into the chamber indicating the line of separation, unless the extent of the valve be limited to that of the internal nacreous deposition. The tube of an oval form, 7 lines by 5 in diameter. The calcareous walls $\frac{1}{30}$th of an inch in thickness at the outlet, and about $\frac{1}{30}$th at the opposite extremity. The free valve unequally triangular, with the angles rounded off, about the thickness of a sixpence, moderately concave towards the soft parts, and striated only in the direction of the layers of increment on the outer surface, as in most of the Pyloridean Bivalves of M. de Blainville. The layers gradually increase towards the dorsal edge for a little more than one half of the valve, beyond which the layers continue of almost equal breadth. "This growth of the valve," adds Mr. Owen, "corresponds to the direction in which the chamber is enlarged, which is principally on the dorsal, dextral, and anterior sides: now this is the mode of enlargement best adapted for the full development of the ovary; so that it would seem that the *Clavagella* continues for a time to work its way into the rock without material increase of size, leaving behind it a calcareous tube, which marks its track; after which it becomes stationary, and limits its operations to enlarging its chamber to the extent necessary for the accomplishment of the great object of its existence."

The mantle enveloping the body is like a shut sac, but perforated for the siphon and foot, the opening for the latter being reduced to a small slit. M. Rüppell observed an analogous orifice in the corresponding part in *Aspergillum*, namely, that which is next the sunken sieve-like extremity of the tube, and by which he supposes the water necessary for respiration to be received when the retreating tide leaves exposed the expanded siphonic extremity. Professor Owen is of opinion that this cannot be its use in those species of *Clavagella* which exist at depths too great to allow of their being ever left with the siphonic aperture out of water; but that it must serve to keep up a communication with the neighbouring cavities of the rock, by means of the calcareous tubules, the formation of which is determined by the proximity of these cavities. When therefore the *Clavagella*, by a sudden contraction of the adductor muscles, has forcibly expelled the branchial currents from the siphon, as was observed by Mr. Stutchbury, the space between the free valve and the walls of the chamber would be simultaneously filled, either by water rushing in through the tubules, or forced out from the branchial cavity through the small anterior orifice of the mantle. To assist this operation there is a proportional development of the muscular system, which is remarkably powerful. The impression of the great or posterior adductor is carried two lines beneath the surface of the chamber posteriorly, but gradually rises to the level of the valve. The impression of the smaller anterior adductor is more faint, and is continued into the sinuous pallial impression, which follows the contour of the anterior margin of the valve at about two lines' distance from it. In the free valve the last two muscular impressions are separate. The outer dermoid layer of the mantle is extremely thin, and, where it does not line the valves, is mottled with minute dark spots, less numerous than those on the skin of Cephalopods, and presenting, under the microscope, a glandular appearance. The muscular layer, after forming the siphon and its retractors, is confined to the anterior part of the mantle, where it swells into a thick convex mass of interlaced and chiefly transverse fibres, and forming, Professor Owen supposes, one of the principal instruments in the work of excavation. No fibres could be detected in other parts of the mantle; nor could any be expected in a mantle which had no lobes to be retracted. The siphon, in the contracted state, formed a slightly-compressed cylindrical tube, half an inch in length, and the same in the long diameter, traversed longitudinally by the branchial and anal canals, separated from each other by a muscular septum, extending to the end of the siphon, beyond which the two tubes do not separately extend outwards, agreeing in this respect with *Gastrochæna* and *Aspergillum*. Muscular walls of the siphon two lines in thickness; the septum separating the branchial and anal canals one line; diameter of each canal about one line; inner extremity both of the anal and respiratory tube provided with a valvular fold: terminations beset with short papillæ. The retractor muscles attach the siphon to the posterior adductor on one side, and to the anterior extremity of the oval mass of muscular fibres above mentioned on the other, leaving an intermediate space on both sides the body, which exposes part of the gills and labial tentacles. The muscular mass which bounds the anterior part of the animal's body is oval, one inch three lines long, eight lines broad, and varying in thickness from two to three lines: it is smooth and convex externally, and hollowed out within to lodge the viscera at the base of the foot, for the passage of which it leaves the small orifice above mentioned. The margins attached to the valves are more or less irregular: that affixed to the loose valve is the broadest, being at the ventral extremity three lines in length.

The gills have the same laminated structure as that observed in other bivalves, they are broad and short, corresponding to the form of the animal; and the laminæ, not thin compressed layers, but broad and projecting but little from the sides of the visceral mass, are arranged in three layers instead of two, on either side of the foot.

The digestive system is accordant with the structure of the same part in the other acephalous mollusks. The mouth, a transverse slit, without masticatory or salivary organs, is bounded by the upper and lower labial processes which are continued in the form of two transversely striated pointed tentacles on either side: these prehensile, sensitive, and probably respiratory organs measure each six lines in length, and about one and a half lines in breadth. The œsophagus, after a course of two lines, dilates into a stomach, the sides of which are perforated by the large hepatic ducts. The intestine, after a course of eight lines, forms a small cæcum about one line in length. The intestine, after making three close turns upon itself in the mass of ova and hepatic follicles at the base of the foot, passes in immediate contact with but not through the heart, and then below the posterior adductor, to opposite the posterior orifice of the anal tube. The exterior of the intestine has an irregular honey-combed appearance, from the close adhesion to it of the capsules of the ova. The liver has the same divided follicular structure and green colour as in the other Bivalves.

The nervous system consists of a large and conspicuous ganglion situated at the posterior part of the base of the foot, just above the orifice of the anal tube. Two nervous cords extend from this ganglion, on either side the foot, to the mouth; other branches radiate in the opposite direction to the siphonic and adductor muscles.

The ovary, of a gray colour, forms a mass at the dorsal aspect of the body above the great adductor muscle, and extending ventral on either side the œsophagus and stomach to the opposite end of the base of the foot. All this mass of intestinal folds, hepatic follicles, and ova was covered by a thin membrane. The little muscular process or foot which passes through the anterior slit of the mantle is but four lines long, and half a line in breadth: its possible use may be to apply a solvent to the rock in which the chamber is excavated.

Mr. Broderip observes that we are left to conjecture the causes which operate to determine the animal in the choice of its abode, if indeed it can be called choice, for most probably *Clavagella* is the creature of circumstances, and if, soon after its exclusion from the parent (when Mr. Broderip supposes it to be furnished with its two

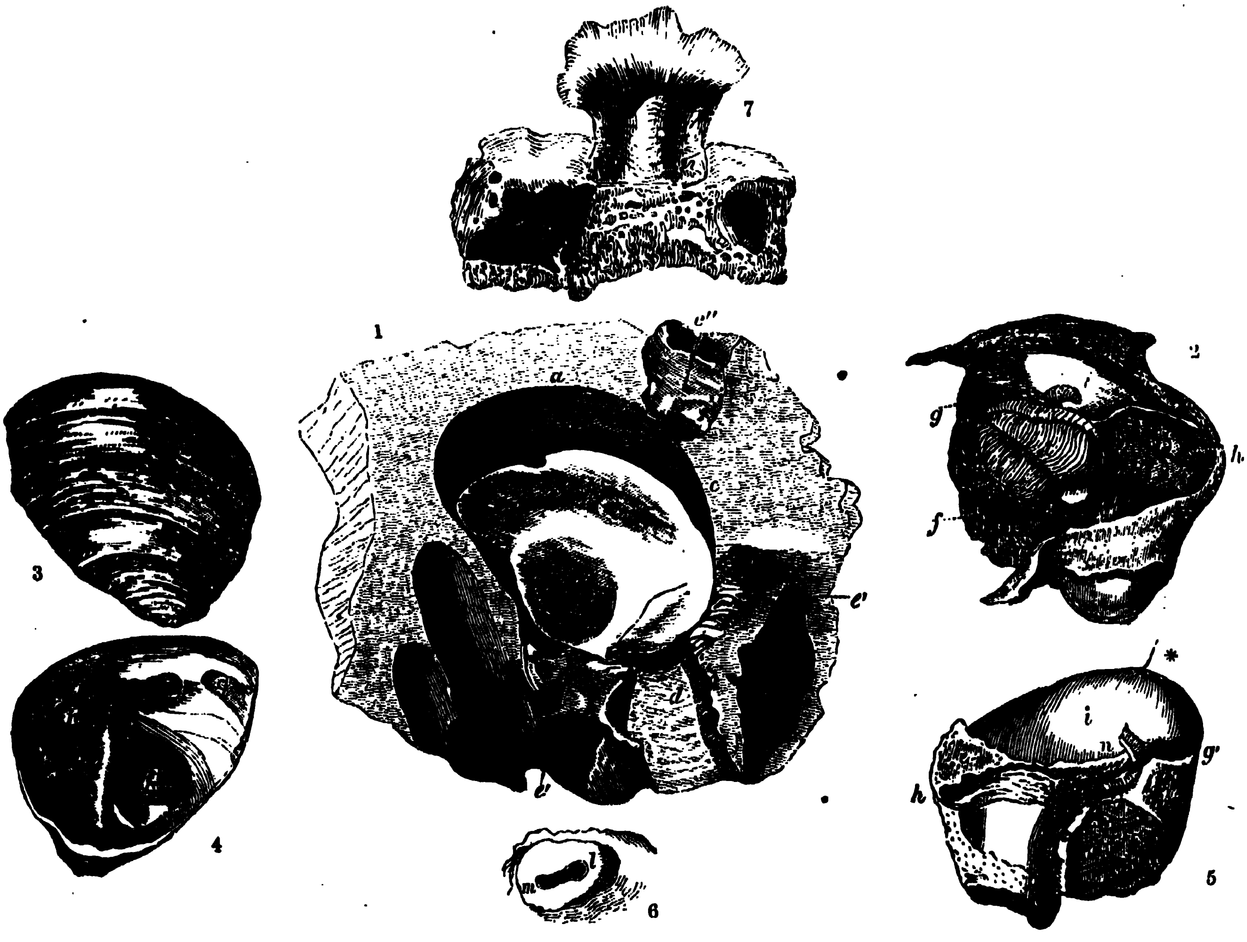


Fig 1, part of calcareous grit rock containing the fixed valve and part of the tube of *Clavagella lata*; fig. 3, external view of the right or free valve; fig. 4, internal view of the same, showing the muscular impressions corresponding with those of the left or fixed valve; fig. 2, soft parts of *C. lata* seen from the right side, the dermal layer of the mantle, *e*, being removed; fig. 5, the same seen from the left side, or that which is in contact with the fixed valve. The extremities of the left labial appendages only are exposed, no part of the gill being protruded. A bristle is placed in the opening of the mantle. *a*, anterior wall of the chamber; *b*, dorsal wall, the letter placed on the hinge of the fixed valve; *c*, ventral wall; *d*, posterior or siphonic outlet; *e*, tubular communications with a neighbouring cavity, here sent off from the posterior part of the mantle; *e′*, calcareous tubes secreted by the above processes and extending into the ties contiguous to the throat of the tube; *e″*, a cavity communicating with nterior part of the chamber; *f′*, impression of the posterior adductor ; *g′*, impression of the anterior adductor muscle; *h′*, impression of the pallial muscle, or third adductor; *f*, posterior or large adductor (the single adductor of the *Ostracea*, *&c.*, corresponds to this, the following are superadded in other families of Bivalves); *g*, the anterior, antero-dorsal, or smaller adductor; *h*, the pallial or antero-ventral adductor; *i*, the convex muscular mass continued over the anterior part of the body, and reducing the opening of the mantle to the small slit *, through which a bristle is placed in fig. 5 (this mass is an inordinate development of what forms the muscular margins of the mantle lobes in other Bivalves); *k*, muscular fibres of the siphon; *l* (fig. 6), the respiratory, or ingestive siphonic canal; *m*, the anal or egestive siphonic canal; *n*, the labial or buccal appendage; *t*, the gills: in fig. 2 the right gill is seen partially protruded between the muscular parts of the mantle; *x*, part of the ovary (figures and description from Owen, to whose lucid memoir and illustrations the reader is referred for the anatomy of the internal parts); fig. 7, anterior termination of the shelly tube of *C. aperta*, Sow., from Mr. Sowerby's 'Genera of Recent and Fossil Shells.'

valves only, and to float free, with, perhaps, some voluntary impulse), it arrives at the vacant hole of some small *Petricola*, *Lithodomus*, or other perforating Testacean which suits it, one valve soon becomes attached to the wall of the hole, and then the animal proceeds to secrete the siphonic sheath or tube, to enlarge the chamber according to its necessities, and to form the shelly perforated tubular plate which is to give admission to the water at the practicable part of the chamber. How the excavation is carried on is also doubtful. The chambers of the individuals of *Clavagella australis*, described by Mr. Broderip, were formed in a siliceous grit, those of *C. elongata* in an *Astræopora*, that of *C. lata* in a calcareous grit, and those of *C. Melitensis* in an argillo-calcareous tufa. "If," says the author last mentioned, "the excavation be the work of a solvent secretion, it must be a solvent of extensive power. The situation of the glands, detected by my friend Mr. Owen, leads me to think that they minister in some way to this operation; and I do not see how the anterior or greater end of the chamber can be operated on by mere mechanical attrition with such parts as must have been contiguous to it. It has been objected that any solvent which would act on a calcareous rock would equally act on the calcareous shell of the animal; but there is perhaps more of point than of strength in this objection. Without laying too much stress on that law of nature by which chemical and vital forces are placed in a state of hostility, and which may or may not be applicable to such a substance as shell, the gland for the secretion of the supposed solvent, as well as the organ for applying it, may be so placed as that the solvent shall only come in contact with the inorganic or dead substance to be acted on without touching the shell. Again, it has been asked, what solvent would act equally on a calcareous and on a siliceous substance? To this it may be answered, first, that it is not pretended that the nature of the supposed solvent is known; secondly, that in siliceous grits, there is more or less calcareous matter by which the mass is held together, and that the solution of the calcareous particles would be followed by the disintegration of the stone. . . . . One observation, arising from the various depths at which the recent species have been found, will not, perhaps, be deemed irrelevant. *C. australis* was so near the surface at low water, that it was detected by its ejection of the fluid; *C. elongata*, from the nature of the coral in which it was chambered, could not have been living far beneath the surface; whereas *C. lata* was dredged up from a depth of 66 feet. Any inferences, therefore, as to the state of submersion of a rock during the life of the fossil species of *Clavagella* which there occur, should be made with caution by the geologist."

The geographical distribution of the genus, though now comparatively rare in cabinets, is probably wide. A sharp investigation of masses of coral and of submerged perforated rocks or stones, particularly in warm climates, is very likely to be rewarded by the discovery of *Clavagellæ*.

With regard to its place amongst the other *Mollusca*, Professor Owen is of opinion that the organisation of *Clavagella*, like that of *Aspergillum* described in the 'Reise von Afrik' of Dr. Rüppell, is modelled on the type of the Acephalous Bivalves; and that it follows most closely, in the variations from that type, the modifications which have been observed in *Gastrochæna*. The lengthened worm-like figure of *Aspergillum* is exchanged in *Clavagella*, observes Professor Owen, for a shorter form with greater lateral development; and instead of the small rudimentary valves, which are enchased, as it were, in the calcareous sheath of *Aspergillum*, we find them here largely developed, and one of them always remaining at liberty, to be applied by a powerful muscular apparatus to those offices which are essential to the forcible expulsion of the fluid in the branchial cavity, and probably to assist in the excavation of its secure abode.

Fossil Clavagellæ.

Mr. Broderip says that no fossil species appear to have been detected below the Supracretaceous group. M. Deshayes, in his tables, gives two living and seven fossil (tertiary) species, and one (*C. aperta*, Sowerby) as found both living and fossil (tertiary). He gives the Mediterranean and Indian Ocean as the habitation of the living animal, and Sicily (Pliocene Period of Lyell) as the locality of the fossil. In his edition of Lamarck he makes the whole number (living and fossil) seven, the seventh and last species being *C. aperta;* but he refers to Rang's 'Manuel' for a second living species. *C. coronata* is found in the London Clay. In Deshayes's edition of Lamarck, the species *C. echinata* is followed by *C. cristata;* and the editor, in a note referred to from the latter, says that these two species should be united, as they only differ in size and age. He also observes that the free valve of *C. cristata*, or of *C. tibialis*, has been placed by Lamarck among the species of *Glycimeris* under the name of *G. margaritacea*. And here we may mention the difficulty of laying down specific characters from the valves, which being, as Mr. Broderip remarks, nearly, perhaps altogether, excluded from the light, colour, at best but a treacherous guide, is absent entirely; while the shape of the chamber and of the valves, together with the comparative roughness or smoothness of their outer surfaces, may depend upon the greater or less degree of hardness of the material in which the chamber is formed.

CLAVELINA. [CLAVELINIDÆ.]

CLAVELINIDÆ, a family of Tunicated *Mollusca*, including the British genera *Clavelina* and *Perophora*. This family may be regarded as uniting together the Compound and Simple Ascidians. Till very recently it was supposed that the animals forming this family belonged to the latter. Milne-Edwards first pointed out that the animals which had been described by Savigny under the genus *Clavelina* were not always, nor even usually, separated from each other; but that they spring, as it were, from a common creeping stem, and multiply by gemmation in the same manner as the Compound Ascidians. Milne-Edwards also pointed out that an animal, described by Mr. Joseph Jackson Lister in the 'Philosophical Transactions' for 1834, was truly an Ascidian. This animal occurs in groups consisting of several individuals, each having its own heart, respiration, and system of nutrition, but fixed on a peduncle that branches from a common creeping stem. The individual animals were connected together by a circulation extending throughout the stem. They are transparent, so that their structure can easily be seen through their membranous covering. Milne-Edwards proposed for these animals the name of Social Ascidians.

Clavelina, Savigny.—The individuals and groups are connected by creeping radiciform prolongations, the animals having elongated erect more or less pedunculated bodies. The branchial and anal orifices without rays; outer tunic smooth and transparent; thorax usually marked with coloured lines.

C. lepadiformis (*Ascidia lepadiformis*, O. F. Müller). Thorax forming a third part of the length of the adult individual, and marked with yellow lines; stomach of a bright orange, placed near the middle of the abdominal portion of the animal; part of the intestines of the same colour. Mr. Alder says this animal is very generally diffused throughout the coasts of Great Britain. He has met with it on the Devonshire, Cornish, and Northumberland coasts, and in Lamlash, Rothsay, and Oban bays in Scotland. Mr. W. Thompson has found it in Ireland.

Milne-Edwards gives the following account of the development of this species:—"If we examine with care the foot of a *C. lepadiformis*, we see that the animal adheres to the soil by more or less numerous radiciform prolongations of the tegumentary tunic; and usually we find also cylindrical filaments, which mingled with these roots and formed externally by the same tissue, creep also on the surface of the soil; but are hollow, and internally furnished with a membranous tube. This tube is continuous with the internal tunic of the Ascidian, and the circulation which is seen in the interior of the abdomen of the latter is equally continued into the appendicular canal. This stalk-like body, which is closed at the extremity, is at first simple, but ramifies as it elongates. When its growth is more advanced, we see developing at the extremities of its branches, or even at different points of its length, tubercles containing in their interior a little organised mass in connection with the internal tube. These tubercles elongate, elevate themselves vertically, and become claviform; the blood which circulates in the stem penetrates the soft and pyriform central mass; but this mass, at first pedunculated and adhering to the inner tunic of the principal canal, soon separates itself, and no longer participates in the circulation of the individual to which it owed its origin. Nevertheless its development continues, and we soon distinguish in it all the principal characteristic traits of the ascidian structure; the branchial sac becomes perfectly outlined without being as yet in communication with the interior; a curved digestive tube is seen beneath the thorax. At length a buccal opening is formed, and the general shape of the young animal approaches more and more nearly that of the adult. Thus there is produced by process of budding a new individual, linked with its parent by a radiciform prolongation of the tegumentary tunic, and which during the first years of its life has a circulation in common with the mother ascidian, but in the end enjoys an independent existence. Still however it may remain in connection with the individual which produced it through the medium of its roots, or it may become completely free by their rupture without any change of consequence in its mode of life." ('Mémoires de l'Institut,' vol. xviii.)

There are several other species of *Clavelina*, and probably many more exist on our own coasts.

Perophora.—The animal discovered by Lister has been thus named by Wiegmann. It is characterised by the individual animals being pedunculated, suborbicular, compressed, attached by their pedicles to creeping tubular processes of the common tunic, through which the blood circulates. Thorax not lineated by granular bands.

P. Listeri is the only species at present known. It is a minute creature, and occurs not unfrequently on the south coasts of England and in the Irish Sea. It lives attached to sea-weeds, and is beautifully transparent. It looks to the naked eye like little specks of jelly dotted with orange and brown, and linked by a silvery winding thread. Mr. Lister's paper describing this animal is entitled, 'On the Structure and Functions of Tubular and Cellular Polypi, and of Ascidiæ.' It is an admirable paper, and was one of the first-fruits of those labours on the improvement of the microscope for which the world is indebted to Mr. Lister.

CLAVICO'RNES, a name given by Latreille to a sub-section of Coleopterous Insects of the section *Pentamera*.

The insects of this sub-section almost always have the [illegible] thickened at the apex, and frequently the terminal joints forming a club: the joints of the tarsi are usually entire.

Such are the principal characters of the sub-section *Clavicornes*, a group in which Latreille includes the families *Scydmænidæ*, *Histeridæ*, *Silphidæ*, *Scaphididæ*, *Nitidulidæ*, *Dermestidæ*, *Byrrhidæ*. It appears to include many genera of insects which, in a natural arrangement, ought not to be associated under one head.

CLAVIGER. [Pselaphus.]

CLAVIPA'LPI (Latreille), a family of Insects belonging to the Tetramerous *Coleoptera*.

The insects of this family are principally distinguished by the antennæ being terminated by a perfoliate club. The tarsi are generally furnished with a velvet-like substance beneath, and have the penultimate joint bilobed; some few however have the tarsi simple. The mandibles are emarginated or dentated at the apex; the maxillæ are armed on the inner side by a tooth-like process; the palpi have the terminal joint large. Many of the species of this group feed upon fungi and boleti, and their form is often rounded and convex. The genera included in the family *Clavipalpi* are *Erotylus*, *Triplax*, *Languria*, *Phalacrus*, *Agathidium*, and some others.

CLAVULI'NA. [Foraminifera.]

CLAY, any natural mixture of earths which breaks down or disintegrates in water, and affords a plastic ductile mixture. It depends upon this property, rather than colour or composition, whether an earthy body belongs to the class of clays. There are many varieties of clay used for different purposes.

Pipe-Clay is of a grayish-white colour, has an earthy fracture, and a smooth greasy feel; it adheres to the tongue, and is very plastic, tenacious, and infusible. Its name shows the purpose to which it is applied. It is found near Poole in Dorsetshire.

Potter's-Clay is of various colours, and disintegrates by exposure to the air; when mixed with sand it is made into bricks and tiles. It is found in Hampshire, Berkshire, Devonshire, and is largely used in the Staffordshire Potteries. The Hampshire clay yielded by analysis—

Silica	51
Alumina	25
Lime	—

with some Oxide of Manganese and water.

Stourbridge Clay has the general properties above described, but is of a dark colour, owing apparently to an admixture of carbonaceous matter. It is most extensively employed in the manufacture of crucibles, and especially for those used in glass-making. It is extremely refractory in the fire. It yielded by analysis—

Silica	57
Alumina	30
Moisture	12·6

A trace of Iron and Carbonaceous Matter.

It appears to have originated from the disintegration of shale.

Brick-Clay, or Loam, varies much in appearance, texture, and composition; its colour is dependent upon the proportion of oxide of iron which it contains. It lies in abundance upon the London Clay, and frequently rests upon an interposed bed of sand. The organic remains found in it are few, but it sometimes contains the teeth of elephants.

London Clay is a very extensive deposit of a bluish clay, except near the surface, where it has often the usual clay colour. It forms the greater part of Middlesex, the whole of Essex and Suffolk, and part of Norfolk, and frequently rises almost to the surface. Some of the lower beds are yellowish-white or variegated. This clay occasionally includes beds of sandstone, and of a coarse argillaceous limestone, of which Parker's Roman Cement is made. It contains also frequently the bones of the crocodile, turtle, &c.

Plastic Clay skirts the London Clay within the London Chalk basin, and it appears also at the Isle of Wight. This formation consists of a variable number of sand, clay, and pebble-beds irregularly alternating, lying immediately upon the chalk; it contains some appearance of coal, decidedly of vegetable origin, pyrites, oyster-shells, and the branches of trees. The sand-beds of the Plastic-Clay formation are the grand reservoir of soft-water from which the deep wells in and around London are supplied.

Kaolin, or *Porcelain-Clay*, is of various shades of white; it is dull and opaque; occurs friable or compact; feels soft to the fingers and adheres to the tongue. It is infusible, and its specific gravity is 2·216. A large tract of this clay, which includes crystals of felspar, quartz, and mica, occurs near St. Austell in Cornwall. The porcelain manufactures of Worcester are supplied from it. According to Wedgwood it consists of 60 parts alumina and 40 silica. It probably arises from the decomposition of felspar. This clay occurs in France, Saxony, and Austria. Various other kinds of clay are met with in different situations; their nature and composition depend upon those of the rocks from the disintegration of which they have been formed; thus slate, steatite, and trap, each yields a different kind of clay.

CLAY-SLATE. [Slate.]

CLEAVAGE, a term employed in Geology to indicate a peculiar fossility in certain (especially argillaceous) rocks, which is independent of, and generally meets at a considerable angle, the surfaces of lamination or deposition. Clay-Slate furnishes the best examples of this phenomenon. [Slate.]

CLEAVERS. [Galium.]

CLEAVLANDITE, a Mineral occurring in wedge shaped masses in the Chesterfield Albite vein, Massachusetts, United States. It is a lamellar variety of *Albite*. [Albite.]

CLEIDOTHÆRUS, a genus of Acephalous *Mollusca* (Conchifers of Lamarck), established by Mr. Samuel Stutchbury for a testaceous animal, the mechanism of whose hinge connecting the two valves differs most materially from that exhibited by other Bivalves.

Shell bivalve, somewhat pearly, inequivalve, involute, attached by the outside of the larger valve. Hinge with a small conical pointed tooth in the free valve, fitting into a corresponding pit in the attached valve. A testaceous rather elongated curved appendage, connected by cartilage, is inserted into a deep cicatrix within each umbo; muscular impressions, two in each valve, lateral: the anterior ligulate; the posterior suborbicular. Muscular impression of the mantle entire. Ligament external. (Stutchbury, modified by G. B. Sowerby.)

M. De Roissy had separated the genus from *Chama*, with which it might be easily confounded by a superficial observer under the name of *Chamostrea*; but he does not seem to have been aware of the appendage, and, as Mr. Stutchbury observes, his name is entirely inapplicable, there being nothing in the shell to connect it with *Ostrea*.

Cleidothærus Chamöides (Stutchbury). Shell involute, brownish-red, internally of a greenish pearly lustre, attached by the anterior side of the right valve, which is of great depth; left valve but slightly convex; the clavicular appendage with a groove on the convex side.

Mr. Stutchbury states that *C. Chamöides* was found attached to sandstone rocks by T. Young, Esq., R.N., together with an *Aspergillum* (perhaps *Agglutinans* of Lamarck), some *Chamæ*, &c., while searching near the entrance of Port Jackson, pointed out to him as the spot where Mr. Stutchbury discovered in 1826 the first living *Clavagellæ*. In general contour this shell has so great a similitude to *Chama*, that, without opening it, there would be no hesitation in pronouncing it to belong to that genus. [Chamacea.]

Mr. G. B. Sowerby is of opinion that, as far as the character of the internal hinge cartilage having an elongated testaceous appendage goes, *Cleidothærus* connects the *Chamæ* of Lamarck with his Myaires.

CLE'MATIS, a genus of Climbing Plants belonging to the natural order *Ranunculaceæ*, and characterised by having a valvate coloured calyx, carpels in a ripe state terminated by long feathery styles, and opposite leaves. The most common species is *C. vitalba*, the Traveller's Joy, which runs over the hedges in many parts of England, loading them first with its copious clusters of white blossoms, and afterwards with heaps of its feather-tailed silky tufts. It is however better known from some of the exotic species being favourite objects of cultivation. *C. flammula*, a species with panicles of small white flowers, is among the most fragrant of plants. *C. cirrhosa*, *C. crispa*, and *C. florida*, are remarkable for the large size of their greenish-white flowers; while the purple or pink bells of *C. viticella*, hanging gracefully from its festooning branches, render that species, when well managed, one of the most elegant and ornamental of climbers. The species of *Atragene*, Siberian and Alpine plants, with finely-cut leaves and delicate purple flowers, considered a peculiar genus by Linnæus, are other species of *Clematis*. They have a climbing habit, and are occasionally seen in gardens; their stems however are apt to become naked, and they are not so generally cultivated as the species of genuine *Clematis*. The leaves of *C. erecta* and *C. flammula* are used by beggars for the purpose of forming artificial ulcers. There are about 100 species of the genus *Clematis*.

All these plants are hardy, but they are impatient of damp in winter. The latter circumstance is therefore to be attended to by those who wish to ornament their gardens with them.

CLEODORA. [Pteropoda.]

CLEO'ME, a genus of Plants belonging to the natural order *Capparideæ*. It has a calyx of 4 almost equal spreading sepals; 4 petals; a torus somewhat hemispherical; 6, rarely 4, stamens; a silique dehiscent, stipitate, or sessile within the calyx.

C. gigantea is a shrubby plant, velvety-pubescent and somewhat clammy; the leaves 7-foliate, with 30 or 40 veins on each side of each leaflet. It has whitish-green flowers, with pinkish filaments and yellow anthers. It is a native of South America. It is a beautiful plant, but has a disagreeable odour and an acrid taste.

C. rosea is an herbaceous unarmed smooth plant, with quinate leaflets, the lower and floral ones ternate, the uppermost ones ovate sessile; the silique smooth, the length of the stipes. This plant has beautifully rose-coloured flowers. It is a native of Rio Janeiro.

There are about fifty species of the genus *Cleome* described; many of them are now referred to the genus *Polanisia*. [Polanisia.] Most of them are worth cultivating on account of their beauty. The shrubby species do best in a rich light soil. They may be propagated by ripened cuttings in a moderate heat under a hand-glass, or by seed. The seeds of the annual species should be sown on a hot-bed in spring, and when the young plants are of sufficient size they may be planted out in the open border, but not before the middle of May. The biennial species must be kept in the stove; they may be propagated by cuttings, as the shrubby species.

CLEO'NUS, a genus of Coleopterous Insects of the section *Rhyncophora* and family *Curculionidæ*. It has the following characters:—Antennæ rather short, the scape not touching the eyes; basal joint of the funiculus nearly obconic, and rather longer than the remaining joints; the joints from the second to the sixth short and coarctate, the seventh stouter, and closely applied to the club, which is oblong-ovate or nearly so; rostrum short and thick, having generally a channel above; eyes oblong and depressed; thorax subconic, slightly constricted anteriorly; elytra elongate, generally furnished with a protuberance near the apex, which is rounded; legs nearly equal; femora unarmed; tibiæ with the apex slightly thickened, and furnished with a short spine.

Of the genus *Cleonus* about 100 species are known; they inhabit Europe, Asia, and Africa. The ground-colour of their body is almost always black, but this is for the most part hidden by the denseness of the little scales with which they are covered. These scales are generally of an ash-like colour, gray, white, or pale-brown, and small patches of two or more of these tints form clouded markings. Dark markings are often produced by the want of these scales on certain parts, the ground-colour of the body then showing itself.

C. sulcirostris may be taken as the type of this genus. It is about two-thirds of an inch in length, of an elongate oval form, and of an ashy or white colour; the rostrum is thick, nearly as long as the thorax, and furnished with three deep longitudinal furrows; the thorax is almost as wide as the elytra at the base, and tapers towards the head; there is a longitudinal pale line in the centre, which is bordered by two broad dark-brown patches; the rest of the thorax is pale, with the exception of a small brown patch on each side; the elytra are of an ashy colour, and have two oblique V-shaped fasciæ near the middle.

This insect is common in various parts of England, and seems more particularly to frequent chalky and sandy situations; it is sometimes found on nettles and thistles, and often crawling on barren sand-hills near the sea-side. Three or four other species are also found in this country. *C. nebulosus* is very common in some parts of Hampshire, and nearly resembles the one above described, but may be at once distinguished by the absence of the sulci on the snout or rostrum: the scales in this species are not unfrequently fed.

CLE'PTICUS, a genus of Fishes, belonging to the section *Acanthopterygii* and family *Labridæ*. *C. genizara* is the only species, and is from the Antilles. It has the following generic characters:—Head obtuse; mouth protractile; teeth minute, barely perceptible to the touch; body elongate, lateral line uninterrupted; dorsal and anal fins covered with scales nearly to their outer margins.

CLE'RIDÆ (*Tillidæ*, Leach), a family of Coleopterous Insects of the section *Malacodermi*. It has the following characters:—Palpi generally clavate; mandibles dentated internally; penultimate joint of the tarsi bilobate; antennæ more or less serrated or terminated by a club; body generally cylindrical and pubescent; head and thorax narrower than the abdomen; eyes emarginated. Most of these insects are found on flowers and some on old trees. The larvæ of those which are known are carnivorous.

The principal genera included in this family are -*Cylindrus*, *Tillus*, *Priocera*, *Axina*, *Eurypus*, *Thanasimus*, *Opilus*, *Clerus*, *Necrobia*, and *Enoplium*.

Clerus is thus characterised:—Maxillary palpi with the terminal joint thicker than the rest, compressed, broadest at the apex, and truncated; labial palpi with the terminal joint securiform; antennæ with the basal joint rather long, the seven following short, the three terminal joints forming a compressed knob of the form of a reversed triangle; tarsi exhibiting only four distinct joints.

Two species of this beautiful genus (*C. apiarius* and *C. alvearius*) are natives of this country, but they are here of rare occurrence, though in Germany, France, and Italy they are common, and are found on the flowers of umbelliferous plants.

C. apiarius varies from one-half to two-thirds of an inch in length, and is very thickly covered with hairs; it is blue; the elytra are red, and have three blue fasciæ, one of which is at the apex.

The larva of this species feeds upon those of the common hive-bee, and is sometimes very destructive to hives.

C. alvearius very much resembles the species just described, differing chiefly in having a blue spot in the region of the scutellum in addition to the three blue fasciæ on the elytra; its larvæ feed upon those of the mason-bees.

CLERUS. [CLERIDÆ.]

CLIMACTERIS. [CERTHIADÆ.]

CLINKSTONE, a grayish blue Rock, consisting principally of Felspar. It passes gradually into gray Basalt, but is distinguished from that rock by its lower specific gravity. When struck with a hammer it rings like iron. It is frequent in volcanic districts. It is also called *Phonolite*.

CLINTONITE (*Seybertite*, *Xanthophyllite* (?), *Holmesite*), a Mineral which occurs crystallised and in imperfectly crystallised masses. Its primary form is an oblique rhombic prism. Cleavage imperfect. Colour copper-red, reddish brown, yellowish brown, and reddish white; streak yellowish gray. Hardness 4·5. Lustre metallic and metallic pearly. Translucent to opaque. In thin laminæ sometimes transparent. Specific gravity 3·098. Found at Amity, Orange County, New York. Analysis by Clemson:—

Silica	17.0
Alumina	37·6
Magnesia	24·3
Lime	10·7
Protoxide of Iron	5·0
Water	3·6

CLI'NUS, a genus of Fishes belonging to the section *Acanthopterygii* and family *Gobioidæ*. It forms one of the sub-divisions of the Blennies, the species of which may be distinguished by their having several ranges of short pointed teeth, the teeth of the external range being the largest. The dorsal fin is either continuous and even, or, in some, with the anterior rays separated from the posterior by an emargination. Like the true Blennies, these fishes have small fimbriated appendages over the eyes.

CLIO. [CLIONIDÆ.]

CLIO'NIDÆ, the *Clio Tribe*, a family of Naked Marine *Mollusca*, placed by Cuvier as the first of his class *Pteropoda*. Lamarck also arranges them under the Pteropods, which he makes an order, but gives them a situation immediately after the *Hyaleidæ*. De Blainville unites the *Pteropoda* and *Gastropoda* of Cuvier in one class *Paracephalophora*, under which the *Pteropoda* form an order with the name of *Aporobranchiata*, which is divided into two families; the first, *Thecosomata*, being provided with a shell, and the second, *Gymnosomata*, comprising those Pteropods which have none. Rang follows this last arrangement, still retaining Cuvier's term *Pteropoda*, but not rejecting De Blainville's, and making the species of *Clio* of Férussac synonymous with the *Gymnosomata* of De Blainville, and the second family of the class *Pteropoda*.

Gymnosomata.—Body of an elongated form, sub-conical, completely naked: two bundles of tentacular suckers at the mouth; no tooth in the upper lip; a small lingual plate bristled with spines.

Rang thus defines the family:—Animal with the head distinct; no intermediate lobe, but one or more fleshy appendages in place of it; a muscular envelope or mantle.

Clio (*Clione*, Pallas).—Body free, naked, more or less elongated, a little depressed, attenuated abaft (aminci en arrière), without any other fins than the lateral appendages. Head very distinct, provided with six long retractile tentacula, divided into two groups of three each, and capable of being entirely concealed in a species of prepuce bearing a small tentaculum on its external side. Mouth entirely terminal and vertical. Eyes sessile, nearly supernal. A sort of sucker or rudiment of a foot under the neck, between the roots of the fins. Vent and termination of the generative apparatus in a single tubercle, situated at the right side of the neck, at the junction of the fin with trunk. Organs of respiration (?).

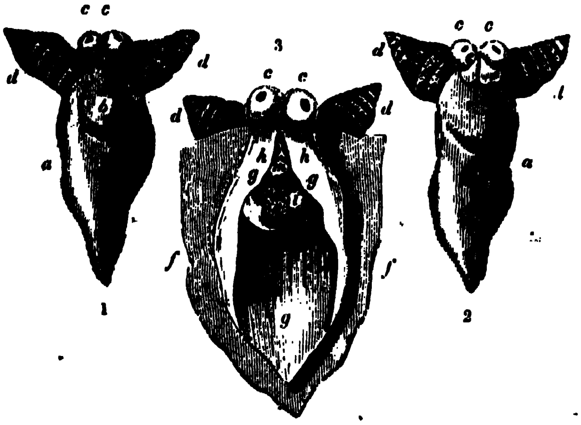
a. Species whose tentacula are well known.

Of these, *C. borealis* and *C. australis* will serve as examples. The former, which appears to be the same with *C. limacina* of Phipps, *C. retusa* of Fabricius, and *Clione papilionacea* of Pallas, is well-known to the whale-fishers and others under the name of 'whale's food.' The species swarms in the northern seas, and indeed so plentiful are thoy that they form a prinsipal part of the food of the whale bone whales. Captain (now Sir W. E.) Parry found it in great abundance in all parts of Baffin's Bay and Davis's Strait, in the neighbourhood of ice. ('Supplement to Captain Parry's first Voyage.') Captain James Ross observes that it is very numerous in most parts of the Arctic Ocean, but less abundant in Regent's Inlet and the Gulf of Boothia. When the weather is calm, they come in myriads to the surface for the purpose of respiration; but scarcely have they reached it when they again precipitate themselves towards the bottom. Cuvier, who gives this account of their habits, adds, that the sea is so glutted with them in certain seasons, that the whales, so to speak, cannot open their mouths without ingulphing thousands of these small mollusks.

Integument, a delicate demi-transparent soft skin, which covers second tunic. This last is thicker, and presents longitudinal and very sensible muscular fibres, which come from two principal bundles attached to the sides of the neck. The effect of these fibres must be to shorten the general envelope of the body, and to approximate its form to a spherical shape. Cuvier, who gives the above description, adds, that he knows not with what the interval between this fleshy tunic and the mass of the viscera is filled in the living state; but observes that it is certain that these do not occupy the half of the area which the tunic incloses; and conjectures that there may be a liquor diffused there, or perhaps only a quantity of air which the animal can compress at pleasure when it would sink in the water, and dilate when it would rise.

The mouth is between the bases of the two tubercles of the head. Below it are two triangular tentacula, which form, as it were, two small wings between the two large ones. The opening of the mouth is triangular; and within are seen some longitudinal wrinkles, which Pallas and Fabricius appear to have taken for teeth, but which have no hardness, and are entirely fleshy. The viscera are connected by vessels and cellulosities which unite them in a small packet situated near the neck. The liver covers the greatest part of them, with the exception of an angle which is occupied by the testicle and ovary.

The œsophagus, of a fair length, descends from the mouth through the neck, and is dilated into a stomach towards the bottom of the mass. Thence the intestinal canal, after having made one fold, proceeds directly to the vent, situated under the gill of the left side. The liver is composed of many lobes and lobules, and envelops the stomach and a great part of the intestinal canal. Two long and straight salivary glands float at the sides of the œsophagus; their excretory ducts are inserted in the mouth. (Cuvier.)



Clio borealis.

Fig. 1, view of the back; *a*, the body; *b*, the viscera, seen through the common integuments; *c*, *c*, the tubercles of the head, and the holes wherein the three tentacula on each side are withdrawn; *d*, *d*, gills and fins. Fig. 2, the same, view of the belly; *a*, *c*, *d*, indicate the same parts as in fig. 1; *e*, the two tentacula placed before the mouth. Fig. 3, *c*, *d*, indicate the same parts as in the two former figures; *f*, *f*, the external tunic or skin; *g*, *g*, the internal tunic or fleshy pannicle; *h*, *h*, the principle bundles of its fibres; *i*, the mass of viscera; *m*, the principal vein of the gills.

The brain consists of two lobes placed at the origin of the œsophagus. From each of these springs a small filament, which swells into a large ganglion that unites itself to its correspondent under the œsophagus. These two ganglions give out each their filaments to the neighbouring parts. Two of these filaments, one on each side, swell again into ganglions, which, uniting together by a new filament that traverses upon the œsophagus, form there a second collar joined to the first beneath; they give out a filament, which is twice swollen or knotted, and it is from these small knots of medullary matter that the different nerves arise. No eye could be perceived, nor any particular organ of the external senses, except the common and general organ of touch. (Cuvier.)

Each gill gives off a vein, which, uniting to its correspondent in the shape of a Y, forms the trunk which reaches the heart. This last, situated in its pericardium on the left side of the mass of viscera, gives out, doubtless, arteries for the whole body, but they could not be followed out. (Cuvier.)

In the reproductive organs they very much resemble the Gastropods, and unite, like them, the two sexes. The ovary gives off a delicate and short oviduct, which reaches the testicle. This last, which at its origin resembles a cæcum, lessens by degrees into a deferent canal, and terminates at a small round purse, which fills the left tubercle of the head, and has its exit near the neck. It is undetermined whether the straight and firm part which terminates the deferent canal is the male organ, or whether that organ is hidden in the small purse above noticed. At the side of this purse is another oblong one, analogous to that which is termed the bladder (la vessie) in the ordinary Gastropods. (Cuvier.)

Dr. Leach says, "In 1811, during a tour made by me to the Orkneys with some friends, I observed on the rocks on that side of the Isle of Staffa, several mutilated specimens of this animal. The three previous days had been extremely stormy so as to confine us to the Isle of Colunsa. Some days afterwards I borrowed from a fisherman a large shrimp-net, and on rowing along the coast of Mull when the sea was calm, after many vain efforts, I was at last enabled to catch one of them alive." This specimen is now in the British Museum; others are in the Museum of the Royal College of Surgeons.

The figures and description above given (Cuvier's) are taken from an individual which had its tentacula, &c., withdrawn.

β. Species without tentacula (?), and whose cephalic enlargement (renflement) is separated from the trunk by a sort of narrow and very distinct thorax. (Genus, *Cliodites* of Quoy and Gaimard.)

Example, *Clio* (*Cliodites*) *caduceus*. De Blainville observes that this species is too incompletely known to allow of a satisfactory conclusion as to what it is; and he even thinks that it may be identical with the *C. australis* of Bruguières.

Pneumodermon.—Animal oblong, sub-cylindrical, divided into two very distinct parts, the anterior conical, the posterior oval. The fins placed near the separation of these two parts, and presenting between them, and on the ventral side, a small membranous appendage. Mouth at the extremity of a sort of retractile proboscis, having, at its base, two bundles of tentacula, each terminated by a small disc or sucker. Gills situated at the posterior part of the body, and disposed somewhat in the form of two C's placed back to back, ƆC, and separated by two small bars. Vent on the right, and a little anterior to the gills. Orifice of the organs of generation in a common tubercle, situated at the root of the fin of the right side.

P. Peronii. This is about an inch in length, and was discovered in the Atlantic Ocean by Péron. The genus was established by Cuvier. De Blainville founded his character upon many well-preserved individuals brought home by Messrs. Quoy and Gaimard from the expedition under Captain Freycinet, and gives Australasia as the locality of the species.
